INDEX TO VOLUME CXIV.

Abbot, S. L. Cases of pericarditis treated with salicylate of sodium, 49, 60; chorea excited by sudden return of hearing: chorea treated with urethran, 419.

Abbott, S. W. Recent progress in public hygiene, 247.

Abdominal Contractions, Rotch, T. M., 242, 252.

Abdominal Surgery. The indications for laparotomy in penetrating stab and shot wounds of the abdomen, Bryant, J. D., 12; exploratory incisions of the abdomen, Polk, W. M., 47; laparotomy in penetrating stab and shot wounds of the abdomen, 65; laparotomy in the treatment of penetrating and visceral injuries of the abdomen, Dennis, W. S., 207.

Abortion. The advisability of inducing abortion in cases of so-called uncontrollable vomiting of pregnancy, Doe, O. W., 121, 132.

Abscess. Pelvic abscess in the male, Burchard, T. H., 495.

Adulteration of food and drugs in New York, 139.

Ætiology of disease, Haven, A. C., 467.

Age. Hygiene of old age, Wood, H. C., 518.

Air. A sterilized atmosphere, Prince, D., 444.

Albumen. Albuminuria in health, Noorden, C. M., 550.

Allen, H. Two instances of adenoid disease of the roof of the pharynx, which exhibited unusual features, 519.

Altitude. The effect of high altitudes on cardiac disease, Loomis, A. L., 471; a statistical inquiry regarding the relation of high altitudes to nervous diseases, Dana, C. L., 492.

Amalgam. Copper amalgam, Rollins, W. H., 175.

Amyloid Degeneration. Localized amyloid degeneration: amyloid lymphoma, Fitz, R. H., 389.

Anæmia. Cases of anæmia, Whittier, E. N., 57; a case of essential pernicious anæmia, Shattuck, F. C., 107.

Anæsthesia. Ether and chloroform once more, 426.

Anatomy. Recent progress in anatomy, Dwight, T., 224; brain of a porpoise, Spitzka, 375; abnormal artery of the pharynx, Farlow, J. W., 437; the arrangements of museums of anatomy, 474.

Antipyrine. Unpleasant effects following antipyrine, Graham, W., 261.

Appendixcæci. Vermiform appendicitis and general peritonitis complicating the puerperal period, Dearborn, J. G., 295.

Army. Hospital nursing corps for the army 42.

Arsenical Wall-papers, 233; arsenic in wall-paper, 401.

Ascites. Permanent drainage in ascites, Caille, A. G., 180.

Ayer, J. Acute articular rheumatism, 157.

Ayer, J. B. Poisoning by three drachms of tincture of belladonna, 10; co-existence of scarlet fever and varicella in a child two and a half years old, 108; eclampsia due to fright or to the shock of an injury, 395; case of scarlet fever (second attack) preceded and followed by a scarlet rash, 252.

Bacillus. The staining of the bacillus of tubercle, Cushing, E. W., 268, 277.

Bacteria, Marcy, H. O., 321; exhibition of preparations of septic bacteria with observations on puerperal septicæmia, Cushing, E. W., 346; a consideration of the bacteria of surgical diseases, Ernst, A. C., 443; a sterilized atmosphere, Prince, D., 444.

Baker, H. B. Causation of pneumonia, 490.

Baker, W. H. Imperforate hymen with retention of the menstrual flux, 290, 295; the treatment of cancer of the uterus, 409, 416.

Bancroft, W. B. The Marine Park, South Boston, as a bathing-place, 478.

Beaumetz, D. Lecture on hypnone, 97.

Becker, A. R. Electricity as a therapeutic agency in gynæcology, 22.

Beckwith, (New Haven.) The treatment of lacerations of the cervix uteri, 570.

Belladonna. Poisoning by three drachms of tincture of belladonna, Ayer, J. B., 10.

Beverly, M. Nerve suturing, 190.

Bibliography. American Surgical Association, Transactions. Vol. III., 351; Bell, A. N., climatology and mineral waters of the United States, 350; Bourneville and Bricon, P., manuel de technique des autopsies, 184; Buck, A. H., a reference hand-book of the medical sciences, embracing the entire range of scientific and practical medicine and allied science, by various writers, 255; Buckley, L. D., acne, its etiology, pathology and treatment, 64; Clowes, F., a treatise on practical chemistry and qualitative inorganic analysis, 90; Corning, J. L., brain rest: being a disquisition on the curative properties of prolonged sleep, 64; Corning, J. L., local anæsthesia in general medicine and surgery, 377; Denison, moisture and dryness: or the analysis of the atmospheric humidities in the United States, 350; Fagge, C. H., the principles and practice of medicine, 328; Flint, A., a manual of auscultation and percussion, 137; Frankland, E., inorganic chemistry, 137; Garnier, M. P., dictionnaire annuel des progrès des sciences et institutions médicales, 622; Gubb, A. S., aids to gynæcology, 17; Hartman, J., facts and mysteries of spiritism learned by a seven years' experience and investigation, 210; Harvard College, annual report of the president and treasurer, 211; Hingston, W. H., the climate of Canada and its relations to life and health, 350; Hueppe, F., the methods of bacteriological investigation, 423; Hudson, E. D., the essentials of physical diagnosis of thoracic diseases, 255; Ireland, W. W., the blot upon the brain, 304; Lund, E., Hunterian lectures on some of the injuries and diseases of the neck and head, the genito-urinary organs, and the rectum, 233; Massachusetts General and Boston City Hospitals, annual reports, 547; May, C. H., manual of the diseases of women, 17; Morris, R. T., how we treat wounds to-day, 304; Otis, F. N., practical clinical lessons on syphilis and the genito-urinary diseases, 424; Page, R. C. W., a chart of physical signs of diseases of the heart and respiratory organs, including thoracic aneurism, 137, 497; Palmer, A. B., the temperance teachings of science, 256; Parker, W., cancer, 401; Peyer, A., an atlas of clinical microscopy, 64; Pick, T. P., fractures and dislocations, 352; Ranney, A. L., practical suggestions concerning the varieties of electrical currents and the uses of electricity in medicine, 64; Remsen, I., an introduction to the study of compounds of carbon: or organic chemistry, 94; Rietschel, H., Lüftung und Heizung von Schulen, Ergebnisse im Amtlichen Auftrage Ausgeführter Untersuchungen, 352; Roberts, J. B., field of limitation of the surgery of the human brain, 41; Sajous, C. E., diseases of the nose and throat, 112; Sée, G., diseases of the lungs, 111; Shepard, J. H., elements of inorganic chemistry, descriptive and qualitative, 90; Smith, J. L., a treatise on the diseases of infancy and childhood, 377; Stewart, F. E., Quiz compend of pharmacy, 574; Thompson, H., on the suprapubic operation of opening the bladder for stone and for tumors, 424; Tyson, J., a guide to the practical examination of the urine, 64; Warlomont, E., a manual on animal vaccination, preceded by considerations on vaccination in general, 256; Webber, S. G., a treatise on nervous diseases, 40; Wilson, J., drainage for health, or easy lessons in sanitary science, 352; Weisse, F. D., practical human anatomy: a working guide for students of medicine and a ready reference for surgeons and physicians, 280; Wise, T., Alpine winter in its medical aspects, with notes on Davos Platz, Wiesen, St. Moritz and the Maloja, 40; Wolff, L., applied medical chemistry, 17.

Bidwell, W. B. A case of fractured skull, with autopsy, 294.

Biggs, H. M. The etiology of rabies and the method of M. Pasteur for its prevention, 298.

Biography. Baldwin, W. O., 528; Bethune, G. A., 336; Bochefontaine, 308; Brownell, W. P., 24, 96; Cobbold, E., 308; Codding, G. H., 398; Collins, I. G., 398; Deschambre, A., 140; Dyer, A. D., 360; Farnham, H. P., 577; Flint, A., 259, 264, 286; Goodenough, L., 360; Green, J. O., 24, 120; Griswold, G., 236, 298; Gudden, B. von, 600; Guernsey, D., 398; Hardy, W. L., 428; Hayward, J. McL., 264; Hodgson, G. W., 523; Hutchins, S., 120; Kane, J. H., 308; Lombard, F. H., 168; McCoughlin, J. A., 164; Morse, H. G., 480, 524; Ollier, L. X., 400; Otis, R. M., 288; Parker, D., 456; Pierce, G. W., 480; Post, A. C., 165; Richardson, E. C., 48; Root, O. D., 212; Shepard, W. H. H., 480; Smith, J. H., 216; Trumbull, S., 628; Vanderpoel, S. O., 260; Warner, B. H., 343; Whittemore, J. H., 48, 69, 72, 96, 286; Woodward, R., 24, 46.

Blake, C. J. and Rotch, T. M. Reflex aural symptoms without aural disease: aural disease with reflex symptoms, 419.

Blake, Mary E. Poem at annual dinner of the Massachusetts Medical Society, 567.

Blood. Does the sulphate of quinine, when given in moderate doses, increase the number of the red blood corpuscles? Hare, H. A., 372.

Boardman, W. E. A case of concealed accidental hæmorrhage, 463, 464; tedious labor with remarks on its conduct, 464.

Bone. Tuberculosis of bone, 17.

Boston. The health of Boston for the year 1885, 331.

Bowditch, H. I. Pulmonary œdema rapidly appearing after thoracentesis, 251.

Bowditch, V. Y. Ten months' experience with pneumatic differentiation, 473; homœopathy as viewed by a member of the Massachusetts Medical Society, 584, 605.

Bradford, E. H. Two cases: operation for the cure of spina bifida, and for the radical cure of hernia, 169, 176; the ætiology of lateral curvature, 241, 253; anchylosis of elbow: fracture of elbow: gunshot wound of chest, 252.

Bradford, E. H. and Burrell, H. L. Report of progress in orthopedic surgery, 413.

Brazil. Yellow fever in Brazil; Freire's inoculation, Lane, H. M., 534.

Breast. The prevention of mammary abscess, Edis, 286.

Bremen, L. Essential vertigo, 467.

Brooks, E. The obligation of states and citizens to preserve the health of the people, 517.

Brouardel. Poisoning an infant by its mother's milk, 166.

Brown, F. F. A case of co-existence of scarlet fever and measles, 226.

Brown, W. S. Gynæcological hints and hobbies, 588, 592.

Bryant, J. D. The indication for laparotomy in penetrating stab and shot wounds of the abdomen, 12.

Buckler, T. H. Sparteine at home, 627.
Bullard, W. N. Chronic tea poisoning, 314, 321; a case of lupus erythematosus, 438.
Burchard, T. H. Pelvic abscess in the male, 495.
Burrall, F. A. The treatment of diabetes, 349.
Burrell, H. L. Recent progress in orthopedic surgery, 413.
Butler, R. G. Mitral stenosis, 492.
Cabinet Officers. The health of cabinet officers, 331.
Cabot, A. T. A tumor of the bladder complicated by the presence of a calculus, 7; a case of multiple calculi in the bladder, 8; amputation at the shoulder-joint for sarcoma of the arm, 11.
Caille, A. G. Permanent drainage in ascites, 180.
Calculus. A tumor of the bladder, complicated by the presence of a calculus, Cabot, A. T., 7; a case of multiple calculi in the bladder, Cabot, A. T., 8; urethral calculus, Porter, C. B., 8; pulmonary calculus, Shattuck, F. C., 395.
Canedy, F. J. Post-mortem in a case of measles, with some remarks upon the treatment of pulmonary œdema, 250.
Caput succedaneum, Fifield, W. C. B., 158.
Carbuncle. The treatment of carbuncle, Collins, J., 117.
Carroll, A. L. Case of meningeal extravasation, with remarks on the localization of the superficial lesions, 396.
Causality in disease applied to the phenomenon of vomiting in pregnancy, Kelly, J. E., 337, 345.
Cephalotome, Reynolds, E., 296.
Cerebral Surgery, 41.
Cimball. The mechanical treatment of pleuritic effusion, 381.
Circulatory System. A case of cyanosis, Spring, C. W., 4; pericarditis treated with salicylate of sodium, Abbot, S. L., 49, 60; a case of ulcerative endocarditis, Purser, 141; parietal thrombus of the aorta, Gannett, W. W., 158; report on recent progress in thoracic diseases, Shattuck, F. C., 199; a case of perforating ulcer of the stomach, opening into the left ventricle and causing death by hæmorrhage, Finney, 285; abnormal artery of the pharynx, Farlow, J. W., 437; traumatic aneurism of the internal carotid artery, Prewitt, T. F., 446; the effect of certain physiological principles that have been noticed in aid of the circulation of the blood, 467; the effect of high altitudes on cardiac disease, Loomis, A. L., 471; a preliminary account in regard to circulatory and respiratory changes observed in animals placed in the pneumatic cabinet, Donaldson, F., 472; mitral stenosis, Butler, R. G., 492.
Chaclacayo trephined skull, 412.
Chadwick, J. R. Seven cases of congenital and one of traumatic stenosis or atresia of the female genital canal, 505, 514.
Channing, W. Recent progress in the care of the insane, 291, 318.
Chapin, C. V. Humanized and bovine vaccine virus, 70; humanized virus once more, 143.
Chapin, H. D. Rheumatism of early life, 231.
Chatard, F. E., Jr. Extrusion of fœtal membranes at the seventh month with subsequent retraction, 357.
Cheever, C. A. A case of multiple sarcoma of the skin, 33.
Chemistry. Recent progress in chemistry, Hills, W. B., 272.
Children. A case of tracheotomy in a neonatus, Hanson, H. H., 105; recurrent headache in children and its treatment, Sturgis, R., 128; should infants be nursed at night? Reynolds, J. P., 254; report on diseases of children, Roteh, T. M., 392; artificial feeding of infants, Keating, J. M., 539; rheumatism of early life, Chapin, H. D., 231; the hygiene of the newly-born, 333.
China. Suicide in China, 45.
Chloroform. Ether and chloroform once more, 426.
Chorea excited by sudden return of hearing: chorea treated with urethran, Abbott, S. L., 419.
Clairvoyant doctors and their prescriptions, 354.
Clark, F. C. Preliminary medical education, 298.
Climate. International Congress of hydrology and climatology, 263; recent literature on climatology, 350.
Cocaine. Physiological and therapeutic effects of cocaine, 19.
Coe, H. C. Is disease of the uterine appendages as frequent as it has been represented? 398.
Cohen, J. S. Lupus of the throat, 520.
Coleman, J. S. A case simulating and believed by all consultants to be abdominal pregnancy at full term; laparotomy; cæsarian section and removal of a living child weighing seven pounds, 445.
Collins, J The treatment of carbuncle, 117.
Color Blindness. Physical examination of candidates for the United States naval and military academies, Jeffries, B. J., 407.
" Compound Oxygen," 323.
Conception after curetting of the uterus, 118.
Concussion. A case of concussion followed by paralyses, pointing to hæmorrhage into the fissure of Rolando, Walton, G. L., 3, 11.
Congress. A National Medical Congress, 424.
Contagious Diseases. The cause and cure of contagious diseases, Durgin, S. H., 75, 86.
Cooper Medical College. "God save the Alumni Association of Cooper Medical College," 165.
Cranlometry. The Chaclacayo trephined skull, 412.
Cremation: a conservative view, 258.
Crozier, T. How does irreducible hernia affect life insurance? 177.
Curtin, E. G. Rocky-Mountain fever, 489.
Cushing, E. W. The staining of the bacillus of tubercle, 268, 277; exhibition of preparations of septic bacteria with observations on puerperal septicæmia, 346.
Cushing, H. W. Subluxation of the radial head in children, 77, 85.
Cutaneous System. A case of multiple sarcoma of the skin, Chewer, C. A., 33; report on the progress of dermatology, Tilden, G. H., 367; a case of lupus erythematosus, Bullard, W. N., 438.
Cyanosis. A case of cyanosis, Spring, C. W., 4.
Daly, W. H. The simplest and most efficient treatment of diphtheria, 545.
Dana, C. L. Total trigeminal paralysis, with alternate hemiplegia: the nerve of taste, 302; a statistical inquiry regarding the relation of high altitudes to nervous diseases, 492; tea-poisoning, 406.
Davenport, B. F. Pharmaceutical notes, 6.
Davenport, F. H. Report on progress in gynæcology, 105.
Dearborn, J. G. Vermiform-appendicitis and general peritonitis, complicating the puerperal period, 295.
Death from hæmorrhage into the abdominal cavity during menstruation, Penny, E. J., 357.
DeBlois, T. A. Cases of laryngeal œdema, 571.
Delafield, F. Chronic catarrhal gastritis, 581.
Delavan, D. B. Buccal tuberculosis, 543.
Dengue. Researches in the ætiology of dengue, McLaughlin, J. W., 468.
Dennis, F. S. Laparotomy in the treatment of penetrating and visceral injuries of the abdomen, 207.
Dentistry. Copper amalgam, Rollins, W. H., 175; recent progress in dentistry, Rollins, W. H., 511, 536.
Diabetes. Post-partum glycosuria, Minot, F., 254; diabetes and perforating ulcer of the foot, 210; the significance of small quantities of sugar in the urine, McBride, T. A., 348; the treatment of diabetes, Burrall, F. A., 349; a case of diabetes in a child-bearing patient, Warner, E., 436; a study of diabetes mellitus, 570.
Diagnosis. A fatal error in diagnosis, 91.
Digestive System. Vaginal and vulvar enterocele, Thomas, T. G., 38; epithelioma of the œsophagus, Grauer, F., 111; rectal disease of uterine origin, Strong, C. P., 151, 157; operations for the radical cure of hernia, Bradford, E. H., 169, 176; early laparotomy in intestinal obstruction, 186; the surgical treatment of perityphlitis, 257; a case of perforating ulcer of the stomach, opening into the left ventricle of the heart, and causing death by hæmorrhage, Finney, 285; a case of diabetes in a child-bearing patient, Warner, E., 436; diagnostical laparotomy, Johnson, C., 421; recent progress in dentistry, Rollins, W. H., 511, 536; two instances of adenoid disease of the roof of the pharynx which exhibited unusual features, Allen, H., 519; lupus of the throat, Cohen, J. S., 520; artificial feeding of infants, Keating, J. M., 539; chronic catarrhal gastritis, Delafield, 581; the influence of fluids (Boissons) on nutrition and in the treatment of obesity, Robin, A., 602.
Diphtheria. Diphtheria treated by the galvano-cautery, 478; an epidemic of diphtheria traced to its source, Lee, B., 515; the simplest and most efficient treatment of diphtheria, Daly, W. H., 545.
Diseases common to animals and men, 138.
Disinfection. The report of the committee of the American Public Health Association on disinfection and disinfectants, 162.
Dislocations. Subluxation of the radial head in children, Cushing, H. W., 77, 85.
Doe, O. W. The advisability of inducing abortion in cases of so-called uncontrollable vomiting of pregnancy, 121, 132.
Donaldson, F. A preliminary account in regard to circulatory and respiratory changes observed in animals placed in the pneumatic cabinet, 472; the functions of the recurrent laryngeal nerve, 542.
Downes. Action of sunlight on micro-organisms, 166.
Drainage. Permanent drainage in ascites, Caille, A. G., 180; continuous preventive disinfection of house drainage, 517.
Draper, F. W. Recent progress in legal medicine, 129.
Driver, S. W. Treatment of irreducible and strangulated hernia, 178.
Drugs. Adulteration of food and drugs in New York, 139.
Dudley, P. The sanitary significance of sporadic typhoid fever, 540.
Dunn, B. F. Co-existence of scarlet fever and measles, 287.
Durell, T. M. Typhoid fever in Somerville, Mass., 60.
Durgin, S. H. The cause and cure of contagious diseases, 75, 86.
Dwight, T. Recent progress in anatomy, 224.
Ear. Recent progress in otology, Morse, H. L., 154; some of the less common forms of mastoid disease, Green, J. Orne, 341, 348; acute non-suppurative catarrhal inflammation of the middle ear, Sexton, S., 370; chorea excited by sudden return of hearing, Abbot, S. L., 419; reflex aural symptoms without aural disease: aural disease with reflex symptoms, Blake, C. J. and Roteh, T. M., 419.
Edes, R. T. Rapid œdema of the larynx, 108; cases of malignant disease of vertebræ, with "paraplegia dolorosa," 359.
Edis. The prevention of mammary abscess, 286.
Editorials. Tuberculosis of bone, 17; physiological and therapeutical effects of cocaine, 19; a Boston polyclinic, 20; cerebral surgery, 41; contagious ophthalmia in the asylums and residential schools of the city of New York, 42; hospital nursing corps for the army, 42; laparotomy in penetrating stab and shot wounds of the abdomen, 65; the plea of insanity and expert testimony in the Goodwin case, 66; the codex commissioner's report on pepsin, 66, the appointment of surgeons in the Marine Hospital service, 67; the therapeutic inutility of calcic phosphates, 91; the Sloane Maternity Hospital, 91; a fatal error in diagnosis, 91; sewerage and the disposal of sewage in populous places, 113; frozen fruit, 114; raw meat and meat powders, 115; a proposed bureau of public health at Washington, 116; the police and the profession, 138; diseases common to animals and men, 138; adulteration of food and drugs in New York, 139; the report of the committee of the American Public Health Association on disinfection and disinfectants, 162; Venus befriends Æsculapius, 164; ptomaines and leucomaines, 185; early laparotomy in intestinal obstruction, 186; diabetes and perforating ulcer of the foot, 210; annual reports of the president and treasurer of Harvard College, 211; the medical examiner system, 212; arsenical wall-papers, 233; the causation of pleurisy, 235; the surgical treatment of perityphlitis, 257; cremation, a conservative view, 258; Dr. Austin Flint, 258; hereditary stature, 281; the signing of petitions, 282; sanitation in workshops and factories, 282; the relative capacity of the bronchus and lungs, 305; the proposed national bureau of public health, 306; poetry and toxicology, 307; the hydrophobia question, 329; the health of Boston for the year 1885, 330; the health of cabinet officers, 331; the health of Providence during the year 1885, 353; indirect fractures of the skull, 353; clairvoyant doctors and their prescriptions, 354; a patient's account of a case of insomnia, 377; the influence of sewerage and water-supply on the death-rates in cities, 379; insanity in Vermont, 379; arsenic in wall-paper, 401; hysteria and spiritism, 403; the infection of malarial fever, 450; the admission of women to the operating theatres of general hospitals, 452; the annual meeting of the American Medical Association, 452; a National Medical Congress, 424; training-schools for nursing the insane, 425; ether and chloroform once more, 426; the arrangements of museums of anatomy, 474; urethran, another new hypnotic, 475; a day's work at a metropolitan hospital, 476; vanilla poisoning, 476; medical heroism, 497; a State Board of Health again in Massachusetts, 498; the strikes from a medical point of view, 521; glass eating, 522; compound oxygen, 323; annual reports of the Massachusetts General and Boston City Hospitals, 547; the annual discourse before the Massachusetts Medical So-

ciety, 548; medicine of the future, 575; the movement cure in China, 576; the Boylston medal prize, 576; military drill and physical training in the public schools, 598; the death of Dr. Bernhard von Gudden, 600; first annual meeting of the Association of American Physicians, 600; the nature of asthma, 623; the New York Society for the Prevention of Contagious Diseases, 623; the therapeutic uses of cus, 623.

Education. A Boston polyclinic, 20; New York Post-Graduate Medical School and Hospital, 44; annual reports of the president and treasurer of Harvard College, 211; preliminary medical education, Clark, F. C., 298.

Ela, W. Etiology of irreducible and strangulated hernia, 176.

Electricity as a therapeutic agency in gynæcology, Becker, A. R., 22.

Electrodes, Knapp, P. C., 323.

Elliot, J. W. A case of salpingitis with severe symptoms: removal of tubes and ovaries: recovery, 344, 347.

Embryology. Report on histology and embryology, Minot, C. S., 460.

Empyæma. Two cases of empyæma, Rotch, T. M., 242, 252.

Engel, H. A mode of concealing the taste of quinine, 262.

Epidemics. The anticipatory treatment of local epidemics, Storer, H. R., 298.

Epilepsy. Cases of epilepsy treated with borax, Folsom, C. F., 145, 157.

Ernst, H. C. A consideration of the bacteria of surgical diseases, 445.

Ether and chloroform once more, 426.

Expert Testimony. The plea of insanity and expert testimony in the Goodwin case, 66.

Exstrophy of the bladder, Gay, G. W., 6.

Extra-Uterine Pregnancy. A case simultating and believed by all consultants to be abdominal pregnancy at full term, Coleman, J. S., 445; a case of extra-uterine pregnancy of seven years' duration, in which the bones of an adult fœtus were found during an attempt at ovariotomy, Homans, J., 457, 465.

Eye. Recent progress in ophthalmology, Wadsworth, O. F., 31; contagious ophthalmia in the asylums and residential schools of the city of New York, 42; ocular symptoms in renal disease, Williams, H. W., 157; a case of alcoholic paralysis preceded and accompanied by amblyopia ex abusu, with remarks thereon, Standish, M., 361.

Farlow, J. W. Abnormal artery of the pharynx, 437.

Feeding bottle for use in cases of intubation of the larynx, Waxham, F. E., 328.

Fifield, W. C. B. Caput succedaneum: cephalhæmatoma, 158.

Finny. A case of perforating ulcer of the stomach opening into the left ventricle of the heart and causing death by hæmorrhage, 285.

Fischer. Communication of tuberculosis through the food, 358.

Fisher, T. W. Two unusual cases of insanity, probably of syphilitic origin, 488.

Fitz, R. H. Localized amyloid degenerations: amyloid lymphoma, 389.

Flint, A., 250, 286.

Folsom, C. F. Cases of epilepsy treated with borax, 145, 157.

Food. The dietary of the poor, 44; frozen fruit, 114; raw meat and meat powders, 115; adulteration of food and drugs in New York, 139.

Formad, H. F. Tests for organic impurities in water, 515.

Fowler, G. R. The operative treatment of facial neuralgia, 382.

Freire's inoculation: yellow fever in Brazil, Lane, H. M., 534.

Fruit. Frozen fruit, 114.

Fuller, F. C. Case of median nerve suturing, 493.

Funis. Prolapse of the funis, Richardson, W. L., 254.

Galvano-cautery. Diphtheria treated by the galvano-cautery, 478.

Gannett, W. W. Parietal thrombus of the aorta, 158; enlarged prostate: difficult catheterization: question of cystotomy, 292; pathological specimens, 274; should nurses who are tuberculous be allowed the care of children? 385, 295.

Garland, G. M. Some cases of reflex neurosis, 25; 35.

Garrish, J. P. The physician and the pharmacist: their relative duties, 396.

Gay, G. W. Gun-shot wound of thigh, secondary hæmorrhage, ligature of femoral artery, gangrene, pyæmia, embolic pneumonia, death, 4; sarcoma of rib, removal, recurrence, second operation, 5; a case of extrophy of the bladder, plastic operation, surgical scarlet fever, 6.

General Diseases. Sarcoma of rib, Gay, G. W., 5; the etiology of rachitis, Haven, H. C., 27; cases of pericarditis treated with salicylate of sodium, Abbot, S. L., 49; cases of anæmia, Whittier, E. N., 57; typhoid fever in Somerville, Mass., Farrell, T. M., 60; a case of essential pernicious anæmia, 107; co-existence of scarlet fever and varicella in a child two and a half years old, Ayer, J. B., 108; on the limitation of the contagious stage of syphilis especially in its relations to marriage, Otis, F. N., 147; acute articular rheumatism, Ayer, J., 157; diabetes and perforating ulcer of the foot, 210; a case of co-existence of scarlet fever and measles, Brown, F. F., 224; rheumatism of early life, Chapin, H. D., 231; post-mortem in a case of measles, with some remarks upon the treatment of pulmonary œdema, Canedy, F. J., 250; paralysis of arm in congenital syphilis, Rotch, T. M., 242, 252; the etiology of rabies and the method of M. Pasteur for its prevention, Biggs, H. M., 298; the hydrophobia question, 329; the significance of small quantities of sugar in the urine, McBride, T. A., 348; the treatment of diabetes, Burrall, F. A., 349; the infection of malarial fevers, 450; the treatment of cancer of the uterus, Baker, W. H., 409, 416; rocky mountain fever, Curtin, R. G., 489; and epidemic of diphtheria traced to its source, Lee, B., 515; a study of diabetes mellitus, 570.

Generative System. Vaginal and vulvar enterocele, Thomas, T. G., 38; six successful cases of ovariotomy, Pinkham, J. G., 53; dilatation of phimosis, Harwood, C. W., 85; report of progress in gynæcology, Davenport, F. H., 105; conception after curetting of the uterus, 118; rectal disease of uterine origin, Strong, C. F., 151, 157; polypus resembling inverted uterus, Minot, F., 202; a case of retraction of the penis, Ivanoff, A. A., 162; imperforate hymen, with retention of the menstrual flux, Baker, W. H., 290, 295; vermiform-appendicitis and general peritonitis, complicating the puerperal period, Dearborn, J. G., 295; vaginal fibroid tumor, Storer, H. R., 297; epithelioma of the cervix in a case of prolapsus uteri: operation for the removal of the growth, with opening of Douglass's cul-de-sac, and completion of the operation by removal of the whole womb, Goodell, W., 313; laparotomy for pelvic abscess, Jackson, A. R., 323; a case of salpingitis, with severe symptoms, Elliot, J. W., 344, 347; the operation of shortening the round ligaments, with two cases, Harrington, F. B., 390; is disease of the uterine appendages as frequent as it has been represented? Coe, H. C., 398; lipoma testis or a large accumulation of fat in the tunica vaginalis, Park, R., 447; the treatment of cancer of the uterus, 409, 416; acute inversion of the uterus, Weeks, A. P., 418; subcutaneous division of urethral stricture, Mastin, C. H., 465; seven cases of congenital and one of traumatic stenosis or atresia of the female genital canal, Chadwick, J. R., 505, 514; the treatment of lacerations of the cervix uteri, Beckwith, 570.

Gihon, A. L. Economic sanitation, 516.

Gilbert. Pneumonia, 571.

Glands. Enlarged cervical glands, Vickery, H. F. 219, 229.

Glass Eating, 522.

Glottis. Sudden death from œdema of the glottis, Jones, W. J., 117.

"God save the Alumni Association of Cooper Medical College," 165.

Goodale, W. Epithelioma of the cervix in a case of prolapsus uteri: operation for the removal of the growth, with opening of Douglass's cul-de-sac, and completion of the operation by removal of the whole womb, 313.

Goodwin case. The plea of insanity and expert testimony in the Goodwin case, 66.

Gouley, J. W. S. Sacculation and perforation of the bladder in consequence of chronic retention of urine, 397.

Graham, W. Unpleasant effects following antipyrine, 261.

Grauer, F. Epithelioma of the œsophagus, 111; primary tuberculosis of the kidney, 111.

Green, C. M. Report on obstetrics, 173.

Green, John O. The action of the Middlesex North District Medical Society on the death of Dr. John O. Green, 118.

Green, J. Orne. Some of the less common forms of mastoid disease, 341, 348.

Grinders Consumption. Specimens from lung of a case of "nailers" or "grinders consumption," Wells, F., 396.

Gruening, E. Reflex symptoms in nasal affections, 135.

Gunn, M. Address before the American Surgical Association, 420.

Gun-shot Wounds. Gun-shot wounds of thigh, Gay, G. W., 4; the indications for laparotomy in penetrating stab and gun-shot wound of the abdomen, Bryant, J. D., 12; laparotomy in penetrating stab and gun-shot wounds of the abdomen, 65.

Gynæcology. Report of progress in gynæcology, Davenport, F. H., 105; gynæcological hints and hobbies, Brown, W. S., 588, 592.

Hæmorrhage. Severe hæmorrhage from anti-partum separation of the placenta, with the infusion of sixty-six ounces of salt solution, Harrington, F. B., 197, 296.

Hallucinations. Unilateral hallucinations, Hammond, W. A. 14.

Hamilton, A. McL. Weighted shoes in locomotor ataxia, 60; the experiences of a sleepless clergyman, 478, 526.

Hammond, G. M. A new thermo-cautery, 492.

Hammond, W. A. Unilateral hallucinations, 14.

Hanson, H. H. A case of tracheotomy in a neonatus, 105.

Hare, H. A. Does the sulphate of quinine, when given in moderate doses increase the number of the red corpuscles? 372.

Harrington, F. B. The pulmonary complications of typhoid fever, 28, 37; severe hæmorrhage from ante-partum separation of the placenta with the infusion of sixty-six ounces of salt solution, 197, 296; the operation of shortening the round ligaments, with two cases, 390; results of the intra-venous injection of salt solutions, 481, 488; intra-venous injection of salt solution, 594.

Hartshorne, H. Continuous preventive disinfection of house drainage, 517.

Harvard College. Annual reports of the president and treasurer of Harvard College, 211.

Morse, H. L. Recent progress in otology, 154.
Mortality of the medical profession, 334.
Museums. The arrangement of museums of anatomy, 474.
Musser, J. H. A series of cases of tubercular meningitis, 356; suggestions regarding the prevention of phthisis in mill-hands, 492.
Myxœdema, Putnam, J. J., 10.
Nailers Consumption. Specimens from lung of a case of "nailers" or "grinders consumption," Wells, F., 396.
Nephrectomy on a patient twenty-three months old, Park, R., 448.
Nephritis. Two cases of nephritis varicellosa, Högyes, 261.
Nervous System. A case of concussion followed by paralyses, pointing to hæmorrhage into the fissure of Rolando, Walton, G. L., 3, 11; unilateral hallucination, Hammond, W. A., 14; some cases of reflex neurosis, Garland, G. M., 25, 35; cerebral surgery, 41; weighted shoes in locomotor ataxia, Hamilton, A. McL., 60; cases of functional and organic injury to the central nervous system caused by trauma, Walton, G. L., 102, 109; hysterical paralysis without contracture, Marie, P. and Leite, S., 45; recurrent headache in children and its treatment, Sturgis, R., 128; reflex symptoms in

nasal affections, Gruening, E., 135; cases of epilepsy treated with borax, Folsom, C. F., 145; operation for the cure of spina bifida, Bradford, E. H., 169, 176; a case of pistol-shot wound of the head resulting in abscess of the brain, with a report of the autopsy, Whitman, R., 170, 175; the intra-cerebral tracts, their physiology and its bearing on the diagnosis of lesions of the centrum semiovale, Starr, M. A., 180; a case of softening of the corpora striata, with specimen, Shaw, J. C., 182; mirror-writing and other pathological chirography of nervous origin, Peckham, G., 183; tubercular meningitis cured by iodoform, Nilsson, E., 190; nerve suturing, Beverly, M., 190; the jumpers, Thornton, J. D., 190; two cases of cerebral tumor, with autopsy, Lane, E. B., 217; paralysis of arms in congenital syphilis, Rotch, T. M., 242, 252; a case of fracture of the skull, followed by abscess, Mason, A. P., 293, a case of fractured skull, with autopsy, Bidwell, W. B., 294; total trigeminal paralysis with alternate hemiplegia: the nerve of taste, Dana, C. L., 302; vaso-motor neuroses, Starr, M. A., 303; neuropathic œdema, 334; a series of cases of tubercular meningitis, Musser, J. H., 356; a case of alcoholic paralysis preceded and accompanied by amblyopia ex abusu, with remarks thereon, Standish, M., 361; brain of a porpoise, Spitzka, 375; a case of neuro-gliomatous hypertrophy of the pons obiongata, Spitzka, 375; a patient's account of a case of insomnia, 377; the operative treatment of facial neuralgia, Fowler, G. R., 382; eclampsia due to fright or to the shock of an injury, Ayer, J. B., 395; case of meningeal extravasation, with remarks on the localization of the superficial lesions, Carrell, A. L., 396; stretching of the facial nerve, Keen, W. W., 448; chorea excited by sudden return of hearing; chorea treated with urethran, Abbot, S. L., 419; sarcoma of brain, Putnam, J. J., 420; essential vertigo, Bremen, L., 467; the diagnostic value of the knee phenomenon or the patellar-tendon reflex in diseases of the nervous system, Zener, P., 468; a statistical inquiry regarding the relation of high altitudes to nervous diseases, Dana, C. L., 492; a case of median nerve suture, Fuller, F. C., 493; preliminary report of a case (with autopsy) of tubercular disease of the spinal cord, Sachs, B., 493; alleged organic disease of the brain following moderate concussion, Nichols, A. H., 509; the influence of overwork in the production of nervous diseases and insanity, Mills, C. K., 553; the functions of the recurrent laryngeal nerve, Donaldson, F., 542; laryngeal vertigo, Knight, F. I., 543; cases of malignant disease of vertebræ, with "paraplegia dolorosa," Edes, R. T., 559; a contribution to the pathology of the respiratory vaso-motor neuroses, Mackenzie, J. N., 572; a case of delirium tremens caused by chewing tea, Slayter, W. B., 578; tendon-jerk and muscle-jerk in disease, Mitchell, S. W., 596.

Neuralgia. The operative treatment of facial neuralgia, Fowler, G. R., 382.

Neuropathic Œdema, 334.

New York Post-Graduate Medical School and Hospital, 44.

Nichols, A. H. Alleged organic disease of the brain following moderate concussion, 509.

Nichols, J. T. G. Differential diagnosis of irreducible and strangulated hernia, 177.

Nightingale. A second Florence Nightingale, 261.

Nilsson, E. Tubercular meningitis cured by iodoform, 190.

Noorden, C. von. Albuminuria in health, 350.

North Carolina epidemic, Wing, C. E., 279.

Nursing. Should nurses who are tuberculous be allowed the care of children? Gannett, W. W., 385, 395; training schools for nursing the insane, 425; hospital nursing corps for the army, 42.

Nutmeg. Poisoning by nutmeg, Lyman, G. H., 61.

Obstetrical Society of Boston, twenty-fifth anniversary, 61.

Obstetrics. Report on obstetrics, Green, C. M., 173.

Œdema. Neuropathic œdema, 334.

Ogle, W. Suicides in England and Wales in relation to age, sex, season and occupation, 357.

Old Remedies, Huse, R. C., 488.

Oleomargarine. The composition and manufacture of oleomargarine, 334.

Ophthalmia. Contagious ophthalmia in the asylums and residential schools of the city of New York, 42.

Orthopraxy. The ætiology of lateral curvature, Bradford, E. H., 241, 251; recent progress in orthopedic surgery, Bradford, E. H. and Burrell, H. L., 413.

Otis, E. O. Some observations on health resorts, 221, 227.

Otis, F. N. On the limitation of the contagious stage of syphilis especially in its relations to marriage, 147.

Ott, D. O. Intravenous injection of saline solution, 262.

Ovariotomy. Six successful cases of ovariotomy, Pinkham, J. G., 53.

Oxygen. "Compound oxygen," 523.

Pancreas. The surgery of the pancreas as based upon experiments and clinical researches, Senn, N., 444.

Paris. Paris letter: Pasteur and hydrophobia, 500, 524.

Park, R. Lipoma testis, or a large accumulation of fat in the tunica vaginalis, 347; nephrectomy on a patient twenty-three months old, 448.

Pasteur. The etiology of rabies and the method of M. Pasteur for its prevention, Biggs, H. M., 298; the hydrophobia question, 329; Pasteur and hydrophobia, 500, 524.

Pathology and pathological anatomy. Recent progress in pathology and pathological anatomy, Whitney, W. F., 483.

Pau. Letter from Pau, 405, 428.

Peckham, G. Mirror-writing and other pathological chirography of nervous origin, 183.

Pelvic Abscess. Laparotomy for pelvic abscess, Jackson, A. R., 323.

Penny, E. J. Sudden death from hæmorrhage into the abdominal cavity during menstruation, 357.

Pepper, W. The causes and distribution of consumption in Pennsylvania, 470.

Pepsin. The codex commission's report on pepsin, 66.

Perforating Ulcer. Diabetes and perforating ulcer of the foot, 210.

Pericarditis. Cases of pericarditis treated with salicylate of sodium, Abbot, S. L., 49, 60.

Perityphlitis. The surgical treatment of perityphlitis, 257.

Perityphlitic Abscess. A successful case of laparotomy for perityphlitic abscess, Homans, J., 388.

Petitions. The signing of petitions, 282.

Pharmacist. The physician and the pharmacist: their relative duties, Garrish, J. P., 396.

Pharmacy. Pharmaceutical notes, Davenport, B. F., 76.

Pharynx. Abnormal artery of the pharynx, Farlow, J. W., 437.

Phimosis. Dilatation of phimosis, Harwood, C. W., 85.

Phosphates. The therapeutic inutility of calcic phosphates, 91.

Phthisis. The causes and distribution of consumption in Pennsylvania, Pepper, W., 470.

Physicians and pathologists, association of, 214.

Physiology. Different physiological senses for heat and cold, Herzen, A., 244; relation of the spleen to the stomach, Johnson, H. L., 238; hereditary stature, 281; does the sulphate of quinine, when given in moderate doses, increase the number of red blood corpuscles? Hare, H. A., 372; the nerve of taste, Dana, C. L., 302; the effect of certain physiological principles that have been noticed in aid of the circulation of the blood, Huston, F. N., 467.

Placenta Prævia. Four cases of placenta prævia, Lovejoy, O. S., 84.

Platt, I. H. The physics and physiological action of pneumatic differentiation, 473.

Pleurisy. The causation of pleurisy, 235.

Pilo-nidal sinus, Porter, C. B., 9.

Pinkham, J G. Six successful cases of ovariotomy, 53.

Pneumatic Cabinet. A preliminary account in regard to the circulatory and respiratory changes observed in animals placed in the pneumatic cabinet, Donaldson, P., 472; a clinical report of cases treated by pneumatic differentiation, Williams, H. F., 473; ten month's experience with pneumatic differentiation, Bowditch, V. Y., 473; the physics and physiological action of pneumatic differentiation, Platt, I. H., 473.

Pneumonia and its treatment, Stockman, C. W., 265; an analysis of 412 cases of lobar pneumonia, occurring at the Massachusetts General Hospital between January 1, 1870 and December 31, 1885, Townsend, C. W., 274; causation of pneumonia, Baker, H. B., 490; pneumonia, Gilbert, 577.

Poetry and Toxicology, 307.

Poisons. Poisoning by three drachms of tincture of belladonna, Ayer, J. B., 40; poisoning by nutmeg, Lyman, G. H., 61; poetry and toxicology, 307; chronic tea-poisoning, Bullard, W. N., 314, 321; chronic tea-poisoning, Dana, C. L., 406; vanilla poisoning, 476; a case of delirium tremens caused by chewing tea, Slayter, W. B., 578.

Police and the profession, 138.

Polk, W. M. Exploratory incisions of the abdomen, 47.

Polyclinic A Boston polyclinic, 20.

Polypus resembling inverted uterus, Minot, F., 202.

Porcher, F. P. Typhoid fever, 596.

Porpoise. Brain of a porpoise, Spitzka, 375.

Porter, C. B. Urethral calculus, 8; caries of tarsus, amputation, 8; excision of knee, 9; pilo-nidal sinus, 9; an uncommonly large fatty tumor, 61; a case of congenital cavernous lymphangioma of the back, 169.

Porter, F. E. Clinical memorandum, 612.

Pousson, A. Two rare varieties of rupture of the bladder, 577.

Post, A. Cases of tumor in hernia region, 486.

Post-Graduate Medical School and Hospital, New York, 44.

Power, W. H. Scarlet fever from the cow, 601.

Precocity. A case of extraordinary sexual precocity, 356.

Pregnancy, affections connected with. Prolonged gestation with anencephalous fœtus, 70; labor during hypnosis, 70; four cases of placenta prævia, Lovejoy, O. S., 84; on a condition of the inner surface of the uterus after the birth of the fœtus, of practical importance, 94; the advisability of inducing abortion in cases of so-called uncontrollable vomiting of pregnancy, Doe, O. W., 121, 132; caput succedaneum: cephalhæmatoma, Fifield, W. C. B., 258; report on obstetrics, Green, C. M., 174; a case of protracted pregnancy, Thomson, A., 196; severe hæmorrhage from ante-partum separation of the placenta, with the infusion of sixty-six ounces of salt solution, Harrington, F. B., 197; prolapse of the funis, Richardson, W. L., 254; vermiform-appendicitis and general peritonitis complicating the puerperal period, Dearborn, J. G., 295; causality in disease applied to the phenomenon of vomiting in pregnancy, Kelly, H. A., 317; extrusion of fœtal membranes at the seventh month, with subsequent retraction, Chatard, F. E., jr., 357; a case of diabetes in a child-bearing patient, Warner, E., 436; a case simulating and believed by all consultants to be abdominal pregnancy at full term, Coleman, J. S., 445; a case of extra-uterine pregnancy, Homans, J., 457, 465; a case of concealed accidental hæmorrhage, Boardman, W. E., 463, 464; tedious labor with remarks on its conduct, Boardman, W. E., 464; results of the intravenous injection of salt solutions, Harrington, F. B., 481, 488.

Prewitt, T. F. Traumatic aneurism of the internal carotid artery, 446.

Prince, D. A sterilized atmosphere, 444.

Pritzl, E. Labor during hypnosis, 70.

Prizes. Astley Cooper prize, 312; the Boylston medical prize, 576; Fiske fund prize, 594.

Providence. The health of Providence during the year 1885, 353.

Ptomaines and leucomaines, 185.

Purser. A case of ulcerative endocarditis, 141.

Putnam, J. J. Myxœdema, 10; sarcoma of brain, 420.

Quinine. A new source of quinine, 141; does the sulphate of quinine, when given in moderate doses, increase the number of the red blood corpuscles, Hare, H. A., 372; a mode of concealing the taste of quinine, Engel, H., 202; use of so-called antipyretic doses of quinine, Schultz, O. F., 468.

Rabies. The etiology of rabies and the method of M. Pasteur for its prevention, Biggs, H. M., 298; the hydrophobia question, 329.

Radius. Subluxation of the radial head in children, Cushing, H. W., 77, 85.

Rags. Importation of foreign rags into American ports, Wilson, F. S., 516.

Rapid transit from a sanitary point of view, 142.

Recent Progress. Eye, Wadsworth, O. F., 31; mental diseases, Stedman, H. R., 80; legal medicine, Draper, F. W., 120; Ear, Morse, H. L., 154; obstetrics, Green, C. M., 173; thoracic diseases, Shattuck, F. C., 199; anatomy, Dwight, T., 224; public hygiene,

Abbott, S. W., 247; chemistry, Hills, W. B., 272; care of the insane, Channing, W., 291, 318; diseases of children, Rotch, T. M., 392; orthopedic surgery, Bradford, E. H. and Burrell, H. L., 413; histology and embryology, Minot, C. S., 460; pathology and pathological anatomy, Whitney, W. F., 483; dentistry, Rollins, W. H., 511, 536; recent progress in laryngology and rhinology, Hooper, F. H., 608.

Reflex Neurosis. Some cases of reflex neurosis, Garland, G. M., 25, 35.

Reflex symptoms in nasal affections, Gruening, E., 135.

Respiratory System. Laryngeal spasm in adults, with report of two cases, one of gouty, the other of undetermined origin, Shattuck, F. C., 1, 9; the pulmonary complications of typhoid fever, Harrington, F. B., 28, 37; rapid œdema of the larynx, Edes, R. T., 108; sudden death from œdema of the glottis, Jones, W. J., 117; reflex symptoms in nasal affections, Gruening, E., 135; adenoid vegetations in the naso-pharyngeal cavity, Hooper, F. H., 193, 202; report on recent progress in thoracic disease, Shattuck, F. C., 193; causation of pleurisy, 235; post-mortem in a case of measles, with some remarks upon the treatment of pulmonary œdema, Canedy, F. J., 241; pulmonary œdema rapidly appearing after thoracentesis, Bowditch, H. I., 251; two cases of empyæma, Rotch, T. M., 242, 252; double pleuritic effusion at thirteen years, Rotch, T. M., 242, 252; pneumonia and its treatment, Stockman, C. W., 265; the staining of the bacillus of tubercle, Cushing, E. W., 268; an analysis of 412 cases of pneumonia, occurring at the Massachusetts General Hospital between January 1, 1870, and December 31, 1885, Townsend, C. W., 274; the relative capacity of the bronchus and lungs, 305; feeding bottle for use in cases of intubation of the larynx, Waxham, F. E., 328; the mechanical treatment of pleuritic effusion, Cimball, 381; pulmonary calculus, Shattuck, F. C., 395; specimens from lung of a case of "nailers" or "grinders consumption," Wells, F., 396; the causes and distribution of consumption in Pennsylvania, Pepper, W., 470; a preliminary account in regard to the circulatory and respiratory changes observed in animals placed in the pneumatic cabinet, Donaldson, F., 472; causation of pneumonia, Baker, H. B., 490; suggestions regarding the prevention of phthisis in mill-hands, Musser, J. H., 492; two cases of adenoid disease of the roof of the pharynx which exhibited unusual features, Allen, H., 519; lupus of the throat, Cohen, J. S., 520; interesting points connected with the larynx, Leidy, J., 540; concerning the positions of paralyzed vocal bands, Hooper, F. H., 541; functions of the recurrent laryngeal nerve, Donaldson, F., 542; observations on the use of some of the newer remedies in diseases of the upper air passages, Shurley, E. L., 543; the simplest and most efficient treatment of diphtheria, Daly, W. H., 545; the question of hæmorrhage after uvulotomy, with the description of an instrument for its arrest, Morgan, E. C., 546; pneumonia, Gilbert, 571; a novel procedure for the removal of subglottic laryngeal growths, Jarvis, W. C., 571; cases of laryngeal œdema, DeBlois, T. A., 571; a case of gummatous disease of the larynx with spontaneous reopening of the larynx after thyroid laryngotomy, Holden, E., 572; gummatous infiltration of the base of the tongue, Hitchcock, U. G., 572; a contribution to the pathology of the respiratory vaso-motor neuroses, Mackenzie, J. N., 572; a case of naso-pharyngeal growth, Johnston, S., 573; what cases of nasal catarrh require surgical treatment, Rice, C. C., 574; recent progress in laryngology and rhinology, Hooper, F. H., 608; the nature of asthma, 623.

Reynolds, E. A new cephalatome, 296.

Reynolds, J. P. Should infants be nursed at night? 254.

Rheumatism. Acute articular rheumatism, Ayer, J., 157; rheumatism of early life, Chapin, H. D., 231.

Rice, C. C. How the therapeutical value of our mineral waters may be increased, 489; what cases of nasal catarrh require surgical treatment, 574.

Richardson, W. L. Prolapse of the funis, 254.

Rickets. The etiology of rachitis, Haven, H. C., 27.

Robin, A. The influence of fluids (Boissons) on nutrition and in the treatment of obesity, 602.

Robinson, Gov. Recommendation to the Massachusetts Legislature on public health, 45.

Rocky-Mountain Fever, Curtin, R. G., 489.

Rollins, W. H. Copper amalgam, 175; recent progress in dentistry, 511, 537.

Rosse, I. C. The Chaclacayo trephined skull, 412.

Rotch, T. M. Six cases occurring in practice, 242, 252; report on diseases of children, 392.

Roth. An old anatomical preparation, 118.

Royal Operation, 358.

Sachs. Preliminary report on a case (with autopsy) of tubercular disease of the spinal cord, 493.

Salem Hospital, 70.

Salpingitis. A case of salpingitis, with severe symptoms, Elliot, J. W., 344, 347.

Salt Solution Severe hæmorrhage from ante-partum separation of the placenta, with the infusion of sixty-six ounces of salt solution, Harrington, F. B., 197, 206; intravenous injection of saline solution, Out, D. O., 262; results of the intra-venous injection of salt solutions, Harrington, F. B., 481, 488.

Sarcoma of rib, Gay, G. W., 5.

Scarlet Fever. Co-existence of scarlet fever and varicella in a child two and a half years old, Ayer, J. B., 108; a case of co-existence of scarlet fever and measles, Brown, F. F., 224; case of scarlet fever (second attack) preceded and followed by a scarlet rash, Ayer, J. B., 252; the co-existence of measles and scarlet fever, Dunn, B. F., 287; scarlet fever from the cow, Power, W. H., 601.

Shultz, O. F. Use of so-called antipyretic doses of quinine in pneumonia, 468.

Senn, N. The surgery of the pancreas, as based upon experiments and clinical researches, 444.

Sewerage. Sewerage and the disposal of sewerage in populous places, 113; the influence of sewerage and water-supply on the death-rates in cities, 379.

Sexton, S. Aural clinic of New York Eye and Ear Infirmary, acute non-suppurative catarrhal inflammation of the middle ear, 376.

Shaw, J. C. A case of softening of the corpora striata, with specimen, 182.

Spleen. Relation of the spleen to the stomach, Johnson, H. L., 239.

Shattuck, F. C. Laryngeal spasm in adults, with the report of two cases, one of gouty, the other of undetermined origin, 1, 9; a case of essential pernicious anæmia, 107; report on recent progress in thoracic disease, 193; pulmonary calculus, 395.

Shattuck, G. B. Acute miliary tuberculosis, 156.

Shoes. Weighted shoes in locomotor ataxia, Hamilton, A. McL., 60.

Shurley, E. L. Observations on the use of some of the newer remedies in diseases of the upper air passages, 545.

Skull. A case of fracture of the skull followed by abscess, Mason, A. P., 293; a case of fractured skull with autopsy, Bidwell, W. B., 294; indirect fracture of the skull, 353.

Slayter, W. B. A case of delirium tremens caused by chewing tea, 578.

Sleep. A patient's account of a case of insomnia, 377.

Sloane Maternity Hospital, 91.

Smart, C. Water-supply of towns and cities, 539.

Smith, A. G. Education and care of the idiot, 364, 373.

Smith, W. E. Pathology of irreducible and strangulated hernia, 176.

Societies. American Climatological Association, 470, 489; American Laryngological Association, 454, 519, 540, 571; American Medical Association, 429, 449, 452, 467; American Medical Editor's Association, 468, 529; American Surgical Association, 420, 443, 465; Association of American Physicians, 395, 600, 613; Boston Society for Medical Improvement, 7, 69, 197, 156, 202, 203, 251, 395, 418; Boston Society for Medical Observation, 85, 252, 347, 488; Boston Medico-Psychological Society, 230, 373; Cambridge Society for Medical Improvement, 206; Chicago Gynæcological Society, 323; Connecticut Medical Society, 568; Essex North District Medical Society, 488; Massachusetts Medical Society, 59, 227, 321, 457, 529, 548, 553, 562, 590; Massachusetts Medico-legal Society, 254, 574; New York Academy of Medicine, 12, 38, 135, 180, 231, 348, 398, 495, 616, New York County Medical Association, 109, 207, 298; New York, Medical Society of the State of, 159; New York Neurological Society, 11, 182, 305, 375, 422; New York State Medical Association, 396; New York State Medical Society, 618; Obstetrical Society of Boston, 61, 158, 254, 295, 464; Philadelphia, Pathological Society of, 89; Rhode Island Medical Society, 297, 594; Pennsylvania State Sanitary Convention, 515, 537; Suffolk District Medical Society, 11, 35, 132, 175, 574, 345, 416, 514, 592.

Somerville. Typhoid fever in Somerville, Mass., Durell, T. M., 60.

Specialists, 319.

Spina bifida Operation for the cure of spina bifida, Bradford, E. H., 169.

Spitzka. Brain of a porpoise, 375; a case of neuroglomatous hypertrophy of the pons oblongata, 375.

Spring, C. W. A case of cystoid, 4.

Stadish, M. A case of alcoholic paralysis preceded and accompanied by amblyobia ex abusu, with remarks thereon, 361.

Stanton. "O Tempora! O Mores!" 570.

Starr, M. A. The intra-cranial tracts, their physiology and its bearing on the diagnosis of lesions of the centrum semi-ovale, 180; vaso-motor neuroses, 393.

Stature. Hereditary stature, 281.

Stedman, H. R. Recent progress in mental disease, 80.

Stevens, G. B. The Improvement's Society's report on the Massachusetts medical examiner system, 238.

Stockman, C. W. Pneumonia and its treatment, 265.

Storer, H. R. Vaginal fibroid tumor, 297; the anticipatory treatment of local epidemics, 298.

Stricture. Subcutaneous division of urethral stricture, Mastin, C. H., 465.

Strikes from a medical point of view, 521.

Strong, C. P. Rectal disease of uterine origin, 151, 158.

Sturgis, R. Recurrent headache in children and its treatment, 128.

Suicide in China, Henry, A., 45.

Suicides in Great Britain, 357.

Surgery. Caries of tarsus, amputation, Porter, C. B., 8; excision of knee, Porter, C. B., 9; amputation at the shoulder-joint for sarcoma of the arm, Cabot, A. T., 11; the indications for laparotomy in penetrating stab and shot wounds of the abdomen, Bryant, J. D., 12; cerebral surgery, 41; American Surgical Association, 420, 443, a consideration of the bacteria of surgical diseases, 443; surgery of the pancreas, Senn, N., 444.

Syphilis. On the limitation of the contagious stage of syphilis, especially in its relations to marriage, Otis, F. N., 147.

Tarsus. Caries of tarsus, amputation, Porter, C. B., 8.

Taste. The nerve of taste, Dana, C. L., 302.

Tea. Chronic tea-poisoning, Bullard, W. N., 314, 321; chronic tea-poisoning, Dana, C. L., 406; a case of delirium tremens caused by chewing tea, Slayter, W. B., 578.

Thermo-cautery, new, Hammond, G. M., 492.

Thomas, T. G. Vaginal and vulvar enterocele, 38.

Thompson, A. A case of protracted pregnancy, 190.

Thornton, J. D. The jumpers, 190.

Tilden, G. H. Report on the progress of dermatology, 367.

Townsend, C. W. An analysis of 412 cases of lobar pneumonia, occurring at the Massachusetts General Hospital between January 1, 1870 and December 31, 1885, 274.

Toxicology. Poetry and toxicology, 307.

Tracheotomy. A case of tracheotomy in a neonatus, Hanson, H. H., 105.

Training-Schools for nursing the insane, 425.

Tubercle. The staining of the bacillus of tubercle, Cushing, E. W., 268, 277; should nurses who are tuberculous be allowed the care of children? Gannett, W. W., 385, 395.

Tuberculosis. Tuberculosis of bone, 17; acute miliary tuberculosis, Shattuck, G. B., 156; buccal tuberculosis, Delavan, D. B., 443.

Tumors. An uncommonly large fatty tumor, Porter, C. B., 61; a study of the etiology of tumors, McNamara, L. J., 109; two cases of cerebral tumor, with autopsy, Lane, F. B., 247; a mediastinal tumor, Whittier, E. N., 289, 395; vaginal fibroid tumor, Storer, H. R., 297; cases of tumors in hernia region, Post, A., 486.

LARYNGEAL SPASM IN ADULTS, WITH THE REPORT OF TWO CASES, ONE OF GOUTY, THE OTHER OF UNDETERMINED ORIGIN.[1]

BY FREDERICK C. SHATTUCK, M.D.

THE irritation which gives rise to laryngeal spasm may be seated within the larynx itself, as in the case of a foreign body, tumor, ulceration, etc.; in the course of the laryngeal nerves, as by the pressure of an enlarged thyroid or bronchial glands; or in the central nervous system, as in locomotor ataxia. In all the above cases, there are definite and localized anatomical changes; but we also meet with spasm of the glottis in cases where an explanation for the symptom is not so easily given, and we are compelled to suppose the existence of a peculiarly irritable condition of the nervous system, depending on defective nutrition, or the presence in the blood of some toxic agent. Spasm occurs, for instance, though rarely, in children apparently free from any other manifestation of rickets; and, when such manifestations are present, we do not know how often enlargement of the bronchial glands may or may not be regarded as the exciting cause. Gueneau de Mussy went so far as to maintain that in swelling of these glands lies the chief, if not invariable, cause of the spasms of whooping-cough, but his views have never won anything like general acceptance.

That the affection which forms the subject of my remarks is much more common in children, and that in childhood — leaving pertussis out of consideration — the largest contingent of cases occurs in connection with rickets, are facts which will not be disputed. For these facts, moreover, the great functional activity of the sympathetic system during the period of most rapid growth, and the consequent unstable equilibrium, seem to afford an adequate explanation.

In adults, apart from foreign bodies and intra-laryngeal tumors, hysteria, or pressure on the recurrent sufficient to excite, but insufficient to abolish the function of the nerve, laryngeal spasm is rare. Its connection with posterior spinal sclerosis has been made out only comparatively recently. That it should occur so seldom in cases of laryngitis, which, in every grade, is so common an affection, is as remarkable as it is fortunate, considering the great discomfort and alarm to which the symptom is apt to give rise. Fatal cases are very rare, but are recorded.

In 1876, Charcot first described, and up to 1879 saw four cases, to which he applied the term laryngeal vertigo. The striking feature of these cases is loss of consciousness following cough, which, in its turn, follows a burning or tickling sensation in the region of the larynx. McBride, in the Appendix to his translation of Gottstein's "Diseases of the Larynx," has collected six other cases, one of which came under his own observation. Charcot is inclined to consider the affection the analogue of Menière's disease, the irritation being conveyed through the superior laryngeal, the sensitive nerve of the larynx, stimulation of which produces spasm of the glottis. McBride and Krishaber, however, seem to think the cases are really simply spasmodic.

In the two cases which I shall now briefly report, laryngeal spasm is the most prominent symptom. In the first case, there certainly seems to be no sufficient cause in the larynx itself, and careful physical examination fails to detect anatomical changes elsewhere at the door of which the symptom can be laid. Lead was found in the urine by a most competent analyst, and this agent is mentioned by Steffen, in his contribution to "Ziemssen's Cyclopædia," as a cause of laryngeal spasm. It has, unfortunately, not been possible to follow up the case, and whether the cause lies really in plumbism, or in functional disturbance of the central nervous system, I cannot determine. In the second case, the spasm seems to be clearly of gouty origin.

January 12th, 1883, Mr. A., forty-eight years of age, a shopkeeper, came to my office, referred to me by Dr. W. H. Workman, of Worcester, and gave the following history. A grandfather had paralysis at the age of sixty, but lived for ten years afterward. No special hereditary tendency to disease was detected. He is the third of a family of eleven, eight of whom are alive and well. Has never used alcohol or tobacco, is moderate with tea and coffee, and eats only twice a day — at 7 A. M. and 2 P. M. — and then rather sparingly. His occupation necessarily involves a good deal of confinement in poor air. The right arm is ill-developed and nearly useless, the result, apparently, of infantile paralysis: he uses the left hand in writing. Twelve years ago, he started in business in Boston, had up-hill work and much anxiety about his affairs until a year or two ago, but kept his worries entirely to himself, not speaking about them even to his wife. Within the last six years or so, has had four attacks of pain in the right hypochondrium, not attended by jaundice; the pain was severe enough to demand morphia subcutaneously, and with each attack, he was laid up for a short time. His physician, a homœopath, pronounced the attacks bilious colic.

Somewhere about the time of the first of the above attacks, he was troubled with hoarseness, and he also noticed that talking fatigued him, sometimes more, sometimes less: these symptoms he attributed to excessive singing, a practice of which he had been very fond. He has never been specially subject to colds, nor does he now take cold easily. His voice has remained more or less hoarse ever since, and talking is a great fatigue to him; so much so, that he generally remains silent at home on returning from his store, and at the store, acts as cashier, in order to avoid, as far as possible, being compelled to talk. He has his good days and bad days, but the use of his voice is seldom unattended by discomfort.

About four years ago he experienced, for the first time, an attack of "choking," a sensation as if he were grasped by the throat, or as if something he had eaten had gone the wrong way. The attack was very distressing while it lasted, and left him very weak for twenty-four hours. He can assign no satisfactory cause for the spasm other than his hoarseness. Very soon after this, he consulted Drs. Bowditch and Knight, who, he reports, detected nothing wrong with him other than a laryngitis. Again, two years ago, he consulted these gentlemen, with a like result. He has now had four of these "choking spells," the last, and by far, the most severe, a few nights since. He went to bed about nine o'clock, as usual, after a day marked by no noteworthy occurrence, and at eleven was awakened out of a sound sleep by a strangling sensation: before he fairly knew what he was doing, he was on his feet, went to the window, opened it, struggled across the

[1] Read before the Boston Society for Medical Improvement, December 28, 1885.

room and back to the window before the spasm relaxed and air could enter his chest. He was very much alarmed by this attack, from which he began to fear he should not recover, and he did not dare to sleep again that night. He felt extremely weak, and kept the house all the next day, as he has done after each attack of the kind. His general health he reports as excellent, but he does not wish a recurrence of the spasm. On laryngoscopic examination, I was surprised to find the evidences of only a slight chronic laryngeal catarrh, no greater than I have often seen in persons not notably hoarse, or otherwise suffering from decided symptoms. A careful examination of the chest and throat externally, failed to detect anything abnormal. The pulse was 84, regular, and the artery felt normal. The left naso-labial fold was less distinct than the other, and the angles of the mouth were not symmetrical, a change which was remarked upon by a friend and noticed by himself perhaps six months ago. The muscles, however, moved properly, and I could detect no other modification of any of the other facial or of the ocular muscles, or of the tongue. The laryngeal changes were so slight it seemed to me not improbable that the source of the spasm lay in some distant part, and I advised the patient to consult Dr. Webber, and have a thorough examination of his nervous system. Dr. Webber reported to me that he found nothing additional, except total deafness of the left ear, but he was inclined to suspect that the attacks of so-called bilious colic might be due to lead. Mr. A. had always taken special pains about his drinking water — he lived out of town — which he was sure was above suspicion; but he was put upon potassic iodide for a week, and the urine was then examined by Dr. Wood, who reported that he found a small amount of lead.

Meantime, the patient used some mild inhalations, and found marked relief to his hoarseness from Wyeth's pellets of chloride of ammonium and chlorate of potash, and one or two other remedies. The relief was, however, only intermittent: February 9th, he reported that he had a slight threatening of spasm that morning, and February 22d, he wrote that he was no better, and has not consulted me since.

In reply to a letter of inquiry from me a few days ago, he says he has had no spasm since February, 1883; his general health is good; there is a constant sensation in his throat as if water were trickling down it; he is obliged to sleep in almost a sitting posture and upon his back — the moment he gets on his side, "that dreadful feeling" comes on. He further reports that talking is quite as painful and difficult for him as it was — to use his own words — "I am never introduced or go into company, if I can possibly avoid it. Some time ago, wife and I went to a friend's birthday party; I was introduced and seated by a lady I never saw before; I could not speak a loud word, and was so mortified, that as soon as I could, I bid our friends good bye, and said I would never go into company again. No one can know how hard it is to bear, except those who are afflicted. I have not had any treatment since I saw you."

The following are Dr. Bowditch's notes of this case: Aged forty-four; consulted me February 1, 1879. (He says that, many years before he had consulted me, and that paralysis of one vocal cord was found. I could find no record of this in my notes). When four years old, he had a fall, striking the back of the head, followed by severe paralysis of the right arm, and partial paralysis since two years after the accident. At the time of visit, this arm was weaker than the other; since the fall, he had had some deafness of the left ear. For three or four months before my seeing him, he had, occasionally, at night, sudden attacks of dyspnœa, from which he would recover easily on sitting up in bed. He had some difficulty in speaking clearly. At times during the day, was hoarse and unable to utter certain words.

Three or four weeks before his visit, had been suddenly seized, while writing at his desk, with a feeling as if he could not breathe. No wheezing, but a croupy, hoarse sound in speaking. He was greatly distressed and thought he was going to die, and as if his heart would cease to beat. During the paroxysms, he became red in the face. Frequent milder attacks in the day, since. Two of the severest paroxysms having occurred the two nights before he called on me. I found that he had no cough nor dyspnœa ordinarily. The thorax was large and vesicular murmur good everywhere. Perhaps a slight difference in lower part of the left back. Percussion everywhere good. No abnormal heart phenomena noticed. He had, in conversation, apparently, severe labor in speaking. Digestion and other functions perfect.

Dr. Knight reported catarrh of the pharnyx, and a few enlarged follicles. There was congestion of the mucous membrane of the arytenoid cartilages and epiglottic folds, quite moderate congestion, also, of the edges of the vocal cords, considerable of the laryngeal surface of the epiglottis. Motion of vocal cords on phonation, but voice altered by mucus between them. Our diagnosis was "Nervous Laryngeal Trouble." No further record made, as the patient did not return.

CASE II. Mr. B., a bachelor of about forty, inherits gout, and has had several acute attacks during the last fifteen years or so. Since he became openly gouty, he has had a number of attacks of laryngeal spasm which come on at night without any obvious exciting cause, wake him from a sound sleep, and are, to use a mild expression, intensely disagreeable.

January 13, 1883, he felt a severe cold coming on, but, having accepted an invitation to a sleighing party, betook himself to the appointed place for starting. His cold was so decided, however, that he withdrew, dined at the Club, went home, and was in bed by ten, taking a hot drink. He soon fell asleep, but towards morning, his brother-in-law, who occupied the room below, was wakened by a heavy fall on the floor, hastened up stairs, and found Mr. B. struggling for breath: the spasm soon relaxed somewhat and he was got to bed, but he suffered much from great oppression in the chest, as well as from recurrent milder attacks of spasm. About 6 A. M., Dr. F. B. Greenough was summoned, and I will make some quotations from a letter he wrote that day, failing to find me at home when he called to ask me to take charge of the case, he confining himself now strictly to special practice.

"The most distressing symptom when I was called was an evident spasm of the larynx, which caused a strident, choking, gasping for breath. The sputa, while I was there, was clear, pure, bright-red blood, without, apparently, any mucus, and there was none of that harassing cough which I have always seen in cases of violent congestion. There were no positive abnormal physical signs in the chest, the pulse was rather small and over 100; he was not blue, nor was his respiration very hurried, but there was this catch in the

larynx, which made it hard for him to draw his breath. He had a feeling of nausea, and I should have given him an emetic had I not feared that vomiting might aggravate the spasm, and that if undigested food were thrown up, it might get down into the trachea. He did throw up a little bilious fluid while I was there, and it gave him an awful spasm of strangling, that was overcome only by a whiff of ether. At one time, I felt that if the symptoms of congestion did not clear up, as they did, it would be a question of the propriety of venesection."

The patient himself reported that the symptoms of congestion were much worse before Dr. Greenough saw him, that the laryngeal spasm alone was, by far, the most severe he had ever had, and that the combination was one which he hoped never again to experience. I saw him first at 2 P. M., January 14, when he was comparatively comfortable. The pulse was 84, full and strong, respiration, 20; temperature, 99.5. The voice was hoarse, and talking was painful; there was marked substernal soreness, but no pain elsewhere in the chest, the examination of which gave negative results. In a cup, was a small amount of sputum, very similar to that of pneumonia. The urine had a density of 1030, was free from albumen, but loaded with lithates. At 9 P. M., the pulse, respiration, and temperature remained the same.

January 15. He reported a fair night, without anodyne, and felt better; he had raised half a dozen bloody sputa during the night. Pulse, 66; respiration, 20; temperature, 98.5. January 16. Further improvement. Pulse, 50; rather small for so large a man. Complained of pain in the back, and of acute pain in the heel, such as he had had in previous gouty attacks. The urine was scanty, with high specific gravity and deposited lithates. Under alkalies and other suitable treatment, the pain in the heel and other symptoms soon cleared up, and in a week, he was in usual health, and there was no recurrence of the spasm. In the following June, the very night after his return from three weeks in the Maine woods, he had his next spasm; this was Thursday night, and Saturday he sailed for Europe, en route for Carlsbad. On reaching London, he was laid up a fortnight with the worst bout of gout he ever has had, but struggled on to the Continent as quickly as he could. He was greatly benefited by his stay in Carlsbad, returned home in September, and ever since, a period of more than two years, has been very well. He has had, during this time, one mild attack of spasm, with several threatenings. He believes that he has found a sure cure for the spasm in a small quantity of pure gin, a flask of which he now invariably keeps at his bedside. With the exception of the attack which has been described in detail, the spasm has never been connected with taking cold.

— The Natural History Museum at Vienna, has just been presented with 708 skulls collected through a series of years by Dr. Weissbach, who was for a long time Director of the Austro-Hungarian Hospital at Constantinople, and was a very distinguished anthropological investigator. Of the collection, 195 are pure Turkish skulls, 131 Greek, 96 Servian or Croat, 48 Hungarian, 43 Armenian, 29 old Byzantine. There are also skulls of Maronites, Albanians, Koords, Asiatic Jews, etc.

A CASE OF CONCUSSION FOLLOWED BY PARALYSES, POINTING TO HÆMORRHAGE INTO THE FISSURE OF ROLANDO.[1]

BY G. L. WALTON, M.D.

The surgical interest of this case lies in the fact that the region of the cortex invaded is an important site for operative interference through the guidance of cerebral localization. Whatever doubt remains regarding the functions of other parts of the brain, the fact is practically established that the motor centres for the opposite side of the body are congregated about the fissure of Rolando, although this conclusion may seem sometimes contradicted through commissural connections and secondary changes in brain structure, incident to inflammatory processes. The symptoms in this case point to a primary circumscribed lesion in this region, without misleading complications.

The patient (admitted to Massachusetts General Hospital, in the service of Dr. Porter), a man of twenty-three, was struck about six weeks ago, while standing on the ice of a stream, by a tree which fell from the bank. One branch struck him on the vertex to the right of the median line, another on the left shoulder. Unconsciousness of some hours followed, on recovery from which he found his left leg powerless. He could not move his left arm, whether simply from pain or from paralysis, he cannot tell. His face was not, at that time, he says, drawn to one side. When brought to the hospital the next day, he was very restless and noisy, complained of headache, had frequent outbursts of crying, seemed, at times, hardly accountable for his actions, answered questions, as a rule, coherently, though in a rather silly manner. He is said to have bled from the nose and left ear after the injury, but nothing of the sort appeared at the hospital. The left shoulder was greatly swollen, front and back, but careful examination revealed nothing beyond severe contusion and considerable ecchymoses (Dr. Porter). The patient, when admitted, could not use the left arm nor leg, and the face was drawn to the right. When I first saw the patient (a week after admission), the face was decidedly drawn to the right, through paralysis of the left facial nerve (of which the lower branches alone were affected). There was almost complete motor paralysis of the left arm, without atrophy. In the left leg was found only paralysis of the peroneal muscles, exaggerated knee-jerk and ankle-clonus. There was no sensory paralysis nor loss of any special sense. The pupils were alike and reacted normally. The patient was still restless, noisy, and emotional. The treatment consisted in ice to the head, bromide of potassium, chloral and ergot, cathartics, and low diet. Improvement has been steady. The leg is now practically well, although a trace of clonus remains. The mental condition is fair; the intelligence is still below par, whether lower than before the accident we have no means of ascertaining. The facial paralysis has persisted, and that of the arm, all motions being possible, but weak. Tendon reflexes are marked at the wrist.

The most probable diagnosis is that of concussion, followed by hæmorrhage (of the common variety into the cavity of the arachnoid) in the fissure of Rolando, on the right. That laceration of the cortex also took place, both locally and by contre-coup, is probable, as evidenced by the extreme restlessness. The paralyses

[1] Shown at a meeting of the Surgical Section of the Suffolk District Medical Society, April 1st, 1885.

must, however, have resulted from hæmorrhage. The principal seat of pressure, at present, if the hæmorrhage is cortical, which seems most probable, must be regarded as the lower part of the fissure of Rolando, involving the centres for movements of the opposite arm and side of the face. Whether this was the original seat of the hæmorrhage, and the paralysis of the leg was due merely to extension of pressure, or whether it gradually worked its way down the fissure, involving arm and leg centres at first, and the face only later, we cannot judge, for the patient's statement that his face was not drawn until after the arm and leg were paralyzed, can hardly be relied on.

A CASE OF CYANOSIS.

BY CLARENCE W. SPRING, M.D., OF FITCHBURG.

LOUIS S., a boy, seven months old, of German parentage, was brought by his mother for treatment of a gastro-intestinal disturbance. The peculiar appearance of the child led to my obtaining the following history. The father and mother had always been well, and there were five other children in good health. Nothing bearing on the present condition was found in the family history. The child was born at full term, and nothing was noticed wrong, the mother said, until it was seven days old. The child then began to have attacks of dyspnœa, and "got blue" about the ears, nose, and the extremities. This condition increased in severity, and at times the breathing would stop, and the child appear as though dead. Dyspnœa soon became continuous, though frequently increased by these severe paroxysms. The child could not nurse and was bottle fed.

Examination showed the child to be fairly well nourished. The ears, nose, and portions of the face together with the hands and feet were deeply cyanosed, and the rest of the body, though only to a comparatively slight extent. The dyspnœa was extreme. Auscultation though difficult, showed the lungs to be apparently well filled with air. A loud murmur was heard over the whole front of the chest, but was most distinct over the middle of the sternum. The time could not be definitely determined. Percussion did not show any enlargement of cardiac area.

About a week after the first visit, the child died in one of these paroxysms of dyspnœa, there being no convulsions.

I performed an autopsy twenty hours after death. Rigor mortis was well marked. On removing the sternum the lungs were found well distended and filling the thorax. Subsequent examination of a portion from the upper lobes showed the anterior part in a condition of atelectasis. Nothing further was observed until the heart was removed, which showed some interesting points. The organ was enlarged, of firm consistency, and somewhat pale in color. There was only one opening into the right auricle; both inferior and superior cavæ evidently joining before they entered as a common trunk. There was but one vessel, the aorta, arising from the ventricles, there being no pulmonary artery nor any evidence of a rudimentary vessel in its place. The aorta came off from the base of the ventricles corresponding in position of origin with the inter-ventricular septum. Internal examination showed an open foramen ovale, and an opening also at the base of the septum ventriculorum which would easily admit the end of the finger. This was continuous above, with the opening of the aorta, which thus freely and equally communicated with both ventricles. The left ventricle was hypertrophied, and its walls thickened. The right ventricle was considerably dilated, and the right auriculo-ventricular opening would admit the thumb easily. Cut sections of the walls showed a pale surface but no fatty degeneration was detected. Owing to the fact that I was not able to complete the autopsy the distribution of the vessels to the lungs could not be determined, nor the other organs thoroughly examined.

This pathological condition, though not extremely rare, is of exceptional interest in this case from the junction of both cavæ before entering the auricle; the perfectly symmetrical arrangement of the aorta over both ventricles; and its complete development, while there was the entire absence of any sign, even rudimentary, of a pulmonary vessel arising from the heart.

The admixture of venous and arterial blood was rendered most perfect in this case by the arrangement above given, and in this fact probably lay the cause of the cyanosis, as well as in the fact that the obstruction in the pulmonary circuit made complete decarbonization of the blood impossible. The fact was illustrated in this instance that cyanosis dependent on cardiac malformation may not begin at birth, though in the majority of cases it begins within the first week. It would seem remarkable that the child lived as long as it did, though on looking at the statistics of Aberle, I find that of one hundred and eighty-six cases, only fifty died before the age of seven months. The nature and extent of the malformation obviously determines the completeness of the compensation and the rapidity of death.

Hospital Practice and Clinical Memoranda.

GUN-SHOT WOUND OF THIGH—SECONDARY HÆMORRHAGE — LIGATURE OF FEMORAL ARTERY—GANGRENE—PYÆMIA—EMBOLIC PNEUMONIA—DEATH.

BOSTON CITY HOSPITAL.

SERVICE OF GEORGE W. GAY, M.D., VISITING SURGEON.

REPORTED BY J. B. BRAINERD, M.D., FORMER HOUSE SURGEON.

WILLIAM C., a healthy, robust Scotchman, eighteen years old, was a seaman on board the British Steamer *Colousay*. In the afternoon of February 28th, 1884, he was brought to the City Hospital in a Police ambulance. There had been a row on board the vessel that day, and, in attempting to wrench a loaded revolver from the boatswain, he received the discharge full in the right thigh.

Examination showed a rounded punctate wound on the extensor surface of the thigh, five inches above the inner condyle of the femur. The clothes and skin about the wound were scorched. There was no hæmorrhage, and the dorsalis pedis pulsated. The knee joint was not implicated, but there was a point of tenderness at the upper part of the popliteal space. The wound was washed with a solution of corrosive sublimate, 1 to 1,500, and dressed with corrosive gauze.

The following day the patient was etherized, and the track of the bullet explored by the little finger down to the sheath of the vessels, which was found to

have been opened, but the femoral was felt pulsating. A counter opening was now made over the popliteal space, and the bullet extracted with dressing forceps. It had pierced Hunter's canal without apparent injury to the vessels.

The bullet was of thirty-two calibre, and slightly flattened at the head. Corrosive dressing. For five days he did well. There was no unusual rise of temperature, and the dressings were not disturbed. That night there were two slight hæmorrhages, easily checked by pressure. The following day he was comfortable, but again in the night, he had two very severe secondary hæmorrhages, which necessitated the use of the tourniquet. A few hours later, the femoral artery was tied, by Dr. Gay, at Scarpa's triangle. This did not control the bleeding. The vessel was now sought for in the wound, and raised on a curved aneurism needle. It showed a complete perforation through the wall about the size of a split pea. The artery was ligated above and below this perforation. Leg was wrapped in cotton batting. He passed a comfortable night. His morning temperature was 101° F. At noon he began to have severe rigors, which continued at short intervals for the next two days. They were accompanied by vomiting, rise of temperature, profuse cold sweats, and great prostration. His foot showed some discoloration, which rapidly extended until the whole leg was gangrenous and sloughing. The line of demarcation formed just above the knee.

March 18th. His general condition having improved somewhat, he was given a very little ether, and the leg was rapidly amputated by Transfixion at the level of the original wound. He rallied somewhat after operation, but in a few days began to fail again. The granulations became pale and watery; the flaps were thick and infiltrated; sinuses riddled the stump in all directions, and pus burrowed freely up the thigh. The appetite failed, diarrhœa was constant, and the urine contained about one-fourth per cent. albumen. His mind, however, remained clear through all. On the 9th of April, a double pneumonia set in, undoubtedly of metastatic origin, which he withstood for three days. He died at midnight April 12th.

Autopsy by Dr. F. W. Draper, medical examiner, thirty-six hours after death. The body was much emaciated, and the skin presented a pale sallow hue. The right thigh had been amputated in its lower third; the end of the stump was ulcerated. The left thigh was not swollen or otherwise altered.

Internal Examination. The left pleural cavity contained sixty-six fluid ounces of red, turbid, sero-purulent fluid, with many flakes of firm lymph. The pleura, both costal and pulmonary, was roughened, reddened, and thickened, by recent inflammation. The right pleural cavity contained eight fluid ounces of clear red fluid, without other indications of pleurisy.

The heart was pale, but otherwise was not remarkable.

The upper lobe of the left lung was compressed and carnified; the lower lobe was in a condition of gray hepatization throughout. Upon its inferior surface appeared the base of a recent embolic infarction; it was dark red, slightly raised, and its diameter was five-eighths of an inch. Section of this showed a conical-shaped nodule, occupying a lobule of the lung, three-quarters of an inch in depth, dark red in color, and of firm consistence. The lower lobe of the right lung was œdematous, but not engorged. Upon its posterior and inferior surfaces were counted five infarctions, varying in size at their base from that of a nickel to that of a split pea.

The pulmonary artery and its branches were examined, but nothing abnormal was detected.

The spleen weighed thirteen and a half ounces; it was very soft, and light red in color. No infarctions were found.

The kidneys were moderately enlarged, very pale in color, and of dense consistence. Their capsules were adherent.

The liver, stomach, and intestines were normal.

The right iliac and femoral artery was of normal appearance till the origin of the profunda was reached. At this point began a firm discolorized clot, occupying the entire lumen of the vessel, closely adherent to the intima, conical at its upper end, and completely occluding the artery, from the profunda downward. The point of ligature was found about three inches below the profunda, and the artery was nearly separated by ulceration under the ligature.

Just below the junction of the two common iliac veins, the *right* iliac vein displayed a broken, friable, nearly decolorized thrombus, occupying nearly its entire lumen, and measuring about an inch in length; its inferior end was pointed. Beyond this, as the external iliac and femoral vein was dissected towards the stump, fragments of coagula were found, mingled with laudable creamy pus. The inner coat of the vein was thick and rough.

The *left* common iliac, external iliac, and femoral veins, from the junction of the iliac outward, contained a decolorized clot like that in vein on the right side, except that it was better formed, more firmly adherent to the intima, and with less inflammation of that coat. In the femoral portion of the vein, the clot tapered into a long, dark red, ribbon-like clot, easily detached. There was not complete occlusion of either the right or the left iliac veins, although very little would be required to make the obstruction complete.

The brain was pale, anæmic, and sodden. Nothing wrong was observed about the meninges or sinuses.

SARCOMA OF RIB.

REMOVAL — RECURRENCE — SECOND OPERATION.

ANNIE L., a Stout Irishwoman of forty, came to Hospital September 28th, 1883. She had a tumor under the right breast, of one year's duration. It came on after lifting a heavy tub of water. She felt as if something had given way at the time, and soon after discovered a little nodule, at a point which had always been tender to touch. Its growth has been gradual since; she thinks it has just about doubled its size in the last six months. There has not been much pain.

Examination showed a rounded, smooth-surfaced tumor about the size of an orange, located over the fifth rib, just beneath the breast. It was firmly attached to the ribs below, and to the skin over it.

Operation by Dr. Gay. An incision was made, under ether, through the tumor. It contained about an ounce of thick, glairy fluid. It was easily peeled out from the surrounding tissues, but had to be cut and scraped from the rib.

A specimen of the growth was sent to Dr. Gannett, who reported: "Tumor sent is a fine specimen of a new growth made up of hyaline cartilage. It is, therefore, a 'chondroma,' and started, in all probability, from the cartilage of the rib."

The patient made a rapid, uninterrupted recovery, union by first intention, and was discharged October 17th, 1883.

Eleven months later, she returned, looking very poorly. She had lost some flesh, and was much reduced in strength. Four months after the first operation, the disease returned, and has increased gradually since, attended by more pain. There are two nodules in the old cicatrix, and a third over the ensiform cartilage. Patient was etherized, and the nodule, together with the old cicatrix, removed. The rib was well scraped with a curette. The nodule over the ensiform cartilage was not attached, and was easily removed. The convalescence was tedious, wound healed by granulation, but in six weeks she was able to go home, October 25th, 1884.

A CASE OF EXSTROPHY OF THE BLADDER.

PLASTIC OPERATION — SURGICAL SCARLET FEVER.

Robert M., nine years old, born in Boston, of Irish parents, has been afflicted since birth with a congenital deformity due to failure of complete development of his genito-urinary system. The pubic bones have failed to form the pubic arch for the support of his abdominal organs. There are large double herniæ extending into partially formed inguinal canals. On the perineum is a patch of scrotal integument, but no scrotal sac or tunica vaginalis. The testes can be felt in the inguinal canals just in front of the herniæ. Between these two herniæ is the exposed bladder, its dark red mucous membrane presenting in three folds or lobes, between which are seen the courses and openings of the ureters. At the base of the bladder is a large, well-formed glans penis, without corpora cavernosa or corpus spongiosum. There is no urethra proper, but on either side of the glans penis is a small opening from which the urine dribbles. The folds of the groin and front of the thighs are constantly bathed in the urine, rendered ammoniacal from the constant cystitis which the exposed bladder is subject to.

November 9th, 1883, the patient was operated on, under ether, by Dr. Gay. A longitudinal flap from the umbilical region, and hingeing on its lower border, was brought down like an apron over the exstrophied bladder, the epidermal surface in apposition with the bladder. Two flaps were now taken from the inguinal regions, their pedicles near the perineum. These were brought up over the "apron flap," and united in the median line. Shirt-button sutures were passed from side to side to prevent stretching of the flaps. Drainage tubes were inserted on either side of the glans penis for the discharge of urine.

Patient did well after the operation, but on the third day he had an attack of surgical scarlet fever, which lasted ten days. A fine erythematous rash appeared over his chest and abdomen, which was preceded by vomiting and loss of appetite. The next day the rash had extended on to the shoulders, and down about the wounds and flaps. The wounds were now covered by grayish sloughs, with thickened edges; the rash extended on to the thigh. In four days the slough had cleared off, leaving healthy granulations beneath. The rash also disappeared without further extension, and unattended by desquamation. No sequelæ followed the attack, and the child improved rapidly.

At the end of two weeks, the flaps were generally adherent to each other, the sutures were removed, but the urine continued to leak from the sides, and through sinuses between and under the flaps. There was a phosphatic deposit formed on the under side of the apron flap, which blocked up the drainage openings, but, by careful daily irrigation with warm water, the incrustation was removed. The glans penis was amputated to give a freer outlet for the urine, and the condition of the boy improved. The flaps healed down, leaving a solid abdominal wall, and the urine all escapes through the aperture. He was fitted, by Messrs. Leach & Greene, with a metalic cap, which catches his urine, and conducts it through a rubber tube into a reservoir suspended between his legs.

The peculiar method of making the flaps adopted in this operation is worthy of special attention, from the fact that, owing to the position of the pedicles, one being above, and two below the exposed mucous membrane, as the tissues contracted, the flaps were not displaced, and the interior of the bladder was not exposed, as is apt to be the case, if the pedicles are all situated above or on the sides of the viscus. It is now over two years since the operation was performed, and the boy's condition is entirely satisfactory. He is fat and rosy, and the urinal catches the water, so that he is not a nuisance to himself and to every one about him. There is no cystitis, and no gravel; in short, the urine is normal, and it all escapes from a small opening in the center of the prominent flaps over which rests the urinal.

Pharmaceutical Memoranda.

PHARMACEUTICAL NOTES.

BY B. F. DAVENPORT, M.D.

A SUBSTITUTE FOR IODOFORM.[1]

IODOL is a dark powder, obtained from "Dippel's Animal Oil." It has but little smell, and is soluble in three parts of absolute alcohol, but only in five thousand parts of water. More than two hundred observations on various diseases, have been made with it in the Royal Surgical Institute in Rome. It was used suspended in glycerine, dissolved in alcohol and glycerine, and as an ointment. Chancres were washed with water, dried, and then sprinkled with iodol powder, and covered with silk-protective, the dressing being changed daily. In six days' time, the base of the chancre began to granulate, and the edges to show signs of commencing cicatrization. Under like treatment, open buboes soon improved and healed up. With single indolent ulcers, it proved equally valuable.

DEODORIZATION OF IODOFORM.[2]

Dr. Stout finds the best effect, without altering the therapeutic effect, are to be obtained from coumarin, vanillin, and cinnamic acid. Combined with one-fifth part of its weight of cinnamic acid, it can be used as a fine powder, the acid acting both as a deodorizer and as an antiseptic. One-ninth part of coumarin covers the odor the best. Dr. Stout recommends that mixture of the fine powders be made, and kept in a stoppered bottle one or two months before use.

GERHARDT'S PLUMBUM CAUSTICUM.[3]

Gerhardt, of the Würzburg Syphilitic Clinic, finds a caustic composed of caustic potash and lead oxide,

[1] Lancet, November 28, 1885.
[2] Therapeutic Gazette, August, 1885, page 511.
[3] Lancet, November 1, 1885.

the best means of removing condylomata, as it does not penetrate deeply, yet will destroy a condyloma in a single sitting. It produces a blackish slough where it has been applied.

PARALDEHYDE AS A HYPNOTIC.[4]

Paraldehyde has been used in the Insane Hospital, at Norristown, Pa., in doses from m. fifty to seventy-five, whereby, in the majority of instances, a quiet sleep of two to seven hours, have been induced in ten to fifteen minutes after its absorption. It seems to have no particular action upon either heart or respiration, as in natural sleep, the subject is easily aroused, but soon drops off again when let alone. No convulsive effect or dreamy stimulation of the mind has been observed, its first effect being apparently upon the cerebral hemispheres. The only undesirable feature thus far observed is the disagreeable odor of the breath, which lasts twelve to twenty-four hours. It does not act as an anodyne.

Dr. Hodgson finds it especially useful over chloral in gout, as it helps to maintain the excretion of urine, well charged with its usual solid constituents. It is, however, objectionable in irritable or inflamed condition of the throat or stomach, being liable to aggravate these. It should be well diluted when taken, and the following is a good preparation for it:

℞

Spts. Chloroform	mxv
Paraldehyde	ʒj
Syr. Aurant.	ʒiv
Mucilag. Acaciæ	
" Tragacanth āā q.s. ad.	ʒiij

S. Take the above at bed-time. It may be repeated in an hour or two, if necessary.

It has been found better to repeat a small dose than to give it in single larger doses.

PHENYLMETHYLACETONE.[5]

This compound acetone Messrs. Dujardin-Beaumetz and Bardet have found to possess very intense hypnotic properties. They claim it to be superior in action to chloral, and even to paraldehyde. Given in doses of 0.05 to 0.15 grams, mixed with a little glycerine and enclosed in a gelatine capsule, it determines a profound sleep, and is especially useful in cases of alcoholism. Like paraldehyde, however, it gives a disagreeable odor to the breath, but this may be an advantage over chloral, in that it will prevent its use being concealed. It has not thus far been found to produce intolerance.

THE AVERAGE COMPOSITION OF MILK[6]

As Reported by the Leading Authorities of the World.

The accompanying tabulated statement, compiled by Professor James F. Babcock, Boston, showing the average composition of milk from the reports of the leading authorities of the world, abundantly fortifies the ground taken in relation to the fixing of a standard of quality for milk. It is this standard against which the milk dealers rebel, claiming that it is much higher than any known facts regarding pure and wholesome milk will warrant. This statement completely refutes their persistent assertions, and leaves them absolutely no ground to stand upon.

Average of a large number of analyses by Boucharlat.	13.30	4.10	9.20	70
Davenport, Milk Inspector of Boston, 1884, Average of 31 cows (Grade Ayshire)	13.32	3.70	9.62	
Cameron — Average of 100 cows of the Russell Farm (England)	13.40	4.40	9.00	70
Cameron — Average of 42 cows at the Agricultural Institute, Dublin.	13.40	4.00	9.40	70
Davenport — Average of 3 diaries of 56 cows.	13.45	3.79	9.66	66
Sharples — Report of American Academy of Sciences — Average of 19 cows.	14.49	4.83	9.66	66
Average of the above 16 authorities.	13.53	3.91	9.62	68

During the month of November, 100 samples of milk, from as many milkmen in the city of Boston, were analyzed at the Milk Inspector's office. Of these, 10 proved to be adulterated, and were complained of in the Municipal Court.

The average of these samples, including the adulterated samples, was as follows:—

Total Solids	13.01
Fat	3.37
Solids not fat	9.64
Ash	.62

If milk, of which 10 per cent. of the samples was known to be adulterated, averages 13 per cent. of solids, does not this show conclusively that 13 is a fair standard for any honest milkmen, or milk producer?

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

DECEMBER, 28, 1885, the president, DR. F. W. DRAPER in the chair.

DR. A. T. CABOT showed the specimens and read the notes of two cases, the first case being

A TUMOR OF THE BLADDER, COMPLICATED BY THE PRESENCE OF A CALCULUS.

The patient, a woman of seventy-three, first noticed ten months ago, that her water was thick and brownish. Within the last four months she has at times noticed blood in the urine, and during the past three

months she has been suffering more or less from pain during and after micturition. The pain in the bladder has been very severe during the last three weeks, and the frequency of urination has increased until within the last week she has emptied the bladder about once in every hour during the night, and every two hours in the daytime.

She applied at the Massachusetts General Hospital in the middle of this month (December) and Dr. F. B. Harrington, who saw her in the out-patient room, passed a sound and detected a stone in the bladder.

By his advice she entered the hospital for operation December 24th. Dr. Cabot operated as follows: a lithotrite was introduced under ether, and the stone, which measured only about a half inch in diameter, was seized and crushed.

After the first crushing no fragments could be found by the lithotrite and the tube and pump did not succeed in removing any. The urethra was accordingly dilated, the finger was introduced, and a tumor was readily detected projecting from near the site of the right ureter. It was a fungus-like mass with a broad base and was perhaps as large as two English walnuts. The tissue beneath this tumor was hard, and suggested the probability of its carcinomatous character.

A vesico vaginal opening was made close to the neck of the bladder. Through this, nipping forceps and a sharp spoon were introduced, and the growth was removed till it was level with the bladder wall. The vesico vaginal opening gave the great advantage that the sharp spoon could be freely used under the guidance of the finger introduced through the urethra, and the growth could thus be removed much more quickly and intelligently than can be done when but one opening is used. Then the finger has to be withdrawn to make way for the instrument, which gropes for the tumor which the finger has just felt.

In the débris which came away was a fragment of calculus that seemed to be about one-half of a small stone, the other half of which had been crushed off with the lithotrite. Very little hæmorrhage followed the operation, and the patient was relieved of much of the pain in her bladder.

On the following day she complained of pain in the right side of the abdomen, the origin of which was uncertain, whether in the bowels, in the peritoneum, or in the kidney.

In regard to the latter organ it was to be remembered that the position of the tumor close to, if not over the bladder opening of the ureter made it possible that the escape of urine might be obstructed, either by the pressure of the growth itself or in consequence of some interference with the ureter, during the operation. There was, however, no definite sign of such obstruction.

The specimen of the tumor, which was shown, had the ordinary appearance of a tolerably firm papillomatous growth.

A CASE OF MULTIPLE CALCULI IN THE BLADDER.

The second case was that of a man aged fifty, with the following history: —

In 1876 he first began to notice the occasional passage of small stones through the urethra. He was operated upon at that time in Hartford, where he was then living. The stones were crushed at many sittings, the débris passing by the natural efforts of urination. He was then free from trouble until 1883, when he again began to pass small stones, and he was operated upon by Dr. Caswell, of Providence, who at one sitting with litholapaxy apparatus, removed a number of calculi, some of which were so large as to require crushing. His troubles returned in 1884, and Dr. Caswell again operated and again removed a number of calculi.

He was now free from trouble until about two months ago when he again began to pass small calculi, at first about the size of canary seed and gradually increasing until within the last ten days he has passed three calculi, each of the size of a lemon seed.

When seen, December 25th, he was suffering considerable discomfort from obstruction to urination. He has never had any sharp pain and has never seen any blood in the urine, which is somewhat cloudy.

December 27th. He was etherized and a curved tube, No. 31, French, passed readily into the bladder. When the pump was applied there was much clicking, but nothing passed. The tube presently clogged, was withdrawn, and in the eye was found a biscuit-shaped calculus measuring exactly half an inch in diameter and weighing eleven and a half grains.

The lithotrite was introduced and another somewhat larger calculus was crushed and pumped out. The bladder was then found to be clear.

The operation was followed by no reaction. The calculi, which were shown, were dark reddish brown in color and apparently composed mainly of uric acid. They were oval and biscuit-shaped, and of very regular forms.

DR. C. B. PORTER showed the specimens and reported the history of four cases as follows: —

URETHRAL CALCULUS.

The patient entered the hospital service of Dr. J. Mason Warren in 1865, at the age of four and a half, his parents having noticed frequent micturition for eighteen months, twelve times in twenty-four hours. There were increasing difficulty and pain in the passage of urine, which had contained blood for three months. There was no steady stream but the urine dripped. He drew continually upon the end of the penis, which was large and inflamed. A stone was detected by sounding under ether, and the urethra was found to be unusually capacious. The stone was removed by Dr. Warren through a perineal incision; a lateral incision being made into the prostate, and a stone the size of a filbert was removed by stone forceps.

Twenty years later he returned with a stone in a pocket in the membranous, or the anterior part of the prostatic urethra, and this was removed by Dr. Porter last month.

CARIES OF TARSUS, AMPUTATION.

The patient, fifteen years old, had sprained his ankle two years before, and entered the Massachusetts General Hospital on crutches, in the summer, with a sinus just below and to the front of the inner malleolus of the left foot. From this there was a discharge. Dr. M. H. Richardson enlarged the opening to admit a finger, removed a small fragment with dressing forceps and curetted the wound. After this he went home but returned September 2d, with the sinus still discharging. The foot was placed upon a posterior wire splint. December 17th, the sinus was discharg-

ing freely. The foot had not been used since September 2d, and Dr. Porter amputated. Besides the bones of the tarsus, a section through the tibia showed that to be diseased.

EXCISION OF KNEE.

L. B., aged five years, first entered hospital, September 29th, 1884, with a history of having had trouble with the knee for one year. He was discharged October 27th, his knee having, during this time, been straightened, under ether, and a dextrine and plaster bandage applied.

Re-entered hospital, May 29th, 1885, to have plaster bandage removed. The knee was found enlarged, bent, and could not be straightened. It was again straightened, under ether, and he went home July 4th, wearing a plaster bandage. November 27th, the plaster bandage was removed, and the knee was found to be swollen, painful, and considerably inflamed. He was unable to walk, and the temperature was slightly raised. December 12th, Dr. Porter straightened the knee and put it on a wire splint. On the 19th, he excised the joint. The cartilages of the joint were disorganized, and the patella was united to the femur.

PILO-NIDAL SINUS.

Two years ago, a small swelling appeared over the sacrum, and then disappeared. Two months ago, a hard lump, as large as an egg, appeared on the left buttock, and gradually increased. It was sore, and was poulticed, causing an abundant discharge. On entering the hospital, there was a well-defined outline of induration over the sacrum, extending upon the left buttock, red, hot, and painful. An incision over the sacrum disclosed a cavity filled with hair, and surrounded by disorganized tissue.

DR. F. C. SHATTUCK read a paper on

LARYNGEAL SPASM IN ADULTS, WITH REPORTS OF TWO CASES.[1]

DR. F. I. KNIGHT said that spasm of the glottis in the healthy adult larynx, was extremely rare. Most cases, even of those reported healthy, would show some local disease. Hyperæsthesia, and great consequent irritability were found in cases where the pathological changes seemed slight. This hyperæsthesia was sometimes seen in the same class of patients, higher in the throat, in those distressing cases of dysphagia from hyperæsthetic inflammation of the pharynx, where the lesions seemed so slight. The prognosis, so far as escape from death was concerned, was certainly good in any case where there was not some serious interference with the pneumogastric or recurrent nerve, reported fatal cases being very rare.

In regard to preventive treatment, any constitutional indications should be met, and morbid conditions of the throat and nose treated. In these cases, not uncommon, where the patient was having a recurrence of spasm every night, during a mild attack of acute laryngeal catarrh, the spasm could usually be prevented by giving a small dose of morphia at bedtime. Sometimes belladonna would answer the purpose, but not so certainly. In many cases, the spasm was developed only by the forced expirations of severe cough, and if [illegible] stinging syrup or candy be taken into the mouth at once, when the patient woke up coughing, it could often be prevented. This kind was often seen in old people, especially old ladies. In those cases where the attack occurred at long intervals, without warning, it was difficult to make efficient provision. If the spasm was prolonged, the subcutaneous injection of morphia, or inhalation of a few drops of chloroform on hot water, should be employed. Nothing in Dr. Knight's experience equalled morphia in allaying the tendency to laryngeal spasm.

DR. S. W. LANGMAID said that he must speak of other apparent causes, somewhat removed from laryngitis. Cases of frightful spasm occur, at times, on applying forceps to a growth, or nitrate of silver to the larynx, and such are certainly largely reflex. Cases like Dr. Shattuck's have come under his notice a number of times. A man may go to bed well and with no cough, may awake, and stagger to a window for breath in great suffering, and may finally get relief. In the speaker's own experience, some such cases have almost no laryngitis, and he believes that the spasm is generally reflex. There is often a pendant uvula to irritate the pharynx, and the patients are almost all gouty. There is some functional trouble with the digestive organs. Cases of laryngeal spasm dependent upon indigestion, are not uncommon in children who have passed the second dentition. He has seen several cases in subjects from eight to eleven years, and in them, has never failed to find the cause in the abdomen. There is still another cause in occlusion of the nostril. In proof of this, the speaker reported the case of a man who was often a sufferer, but who was cured by the removal of an hypertrophied turbinated bone, and cauterization of the base.

DR. F. G. MORRILL said that he had seen two cases of spasm of the larynx, pure and simple. Both patients were women. In the first case, the dyspnœa was promptly relieved by a hyperdermic injection of morphia; but in half an hour there was a return of the trouble and an emetic was given, which proved effective and the respiration afterward remained normal. In the other case the dyspnœa was intense and lasted over five hours. Steam and various other remedies failed to relieve the distress, and tracheotomy seemed imperatively demanded. Before the arrival, however, of the surgeon who was summoned to perform the operation, the spasm relaxed, and the next day no trace of any throat trouble could be detected.

DR. J. J. PUTNAM thought that it is likely there are other muscles of respiration, beside those of the glottis that are concerned at the same time, and recalled the observations of Dr. T. B. Curtis on hydrophobia, as reinforcing the reflex theory of laryngeal spasm.

He mentioned a case of spasm occurring at intervals for a long time, in which lead had been found in the urine. Lead is found, however, so often when it is sought for in nervous disease, that the speaker thought either that our methods of analysis must be faulty, or that the presence of lead without symptoms cannot be extremely rare.

DR. KNIGHT said that he did not deny that the immediate cause was sometimes reflex from indigestion, etc., but said that the irritation was reflected to the larynx because it was diseased, and thereby sensitive, just as we see diseased membrane in the nose swell up from reflex action, responding in a way it could not do if healthy. We see the same thing in bronchial asthma, where we in most cases have a hyperæmia about some old lesion, excited perhaps, by reflex action from the digestive, sexual, or other organs. Local

[1] See page 1 in this number of the Journal.

treatment addressed to the diminution of the hyperæsthetic condition of the larynx would often stop the tendency to spasm at once.

With reference to the spasm produced by introducing instruments and remedies into the larynx, Dr. Knight said that, although well known to laryngologists, the proper method of making applications, when there was danger of spasm, could not be stated too often. The patient should take a deep inspiration and hold his breath while the brush or other instrument was introduced, so that the first respiratory act afterward should be one of expiration. It was better, also, that the next inspiration should be through the nose, and not through the mouth.

DR. T. M. ROTCH remarked that we can often have light thrown on a question of this kind, namely, as to whether these spasmodic attacks in the adult larynx have their origin in the larynx itself or elsewhere, by referring to analogous cases among a class where the disease is especially frequent. As Dr. Knight has observed, and as is generally well-known, a very slight irritation in the larynx, and especially in the child, can produce this spasm, and we must, therefore, eliminate, in our diagnosis, even a suspicion of laryngeal irritation. On the other hand, a neurosis of the larynx from reflex irritation elsewhere is not uncommon where the nervous system is in an especially sensitive condition, both from the age of the patient, and from the combination of bad influences which are brought to bear upon the nervous centres of children among the poorer classes.

Dr. Rotch also said that it so happened that he had for some time had unusual opportunities for studying quite a number of these cases in his clinics at the Boston Dispensary and the City Hospital, where the throat department was directly connected with his own, and where children with this affection in its various phases were examined immediately by the laryngologist in charge, with the result that often nothing abnormal whatever could be detected in the larynx.

Dr. Rotch then mentioned one case of especial interest bearing on this point. A boy eight years old, has for some weeks apparently had spasm of the epiglottis, causing a sound like that of hiccough, recurring every fifteen or twenty minutes. The mother of the child has been so much worried by these attacks, that she has brought the child regularly to both clinics, and the throat has repeatedly been carefully examined. On one day only, was a little redness noticed in the larynx, and on that day the attacks were lessened in frequency, while later, when the spasm was increased in frequency, the larynx appeared perfectly normal. The sound made by the boy during the spasm has lately lost its similarity to hiccough, and is now of a slight gasping or choking character.

The spasm is gradually growing less frequent and less severe as the child's general health improves. No cause, digestive or otherwise, has been discovered beyond a general innervation of the nervous system, resulting in a hypersensitive condition represented by reflex laryngeal spasm.

DR. SHATTUCK in closing the discussion, asked Dr. Knight how often, in this climate, he sees an absolutely normal larynx. In view of the rarity of a perfectly healthy laryngeal mucous membrane, and the small proportion of cases in which one meets with laryngeal spasm, something aside from the catarrh must be the important factor in the production of the spasm. Dr. Morrill's case is a good instance of the hysterical spasm of the glottis. In case I, the anatomical changes are very slight, while the aphasia and spasm are severe, and indicate probably a very excitable and unstable condition of the nervous centres. In case II, the severe cold undoubtedly was a factor, but the gout was a more important one. The patient never had a spasm until after he had his first gouty attack, and stated distinctly that there was usually no connection, which he could detect, between his spasms and any catarrhal condition.

The loss of consciousness does not seem to be an indispensable element in the cases of laryngeal vertigo, so called. In regard to one of Charcot's cases, there is a discrepancy between two of the published reports with reference to this point, and in McBride's case there was no unconsciousness.

MYXŒDEMA.

Dr. J. J. PUTNAM reported the case of a lady whose symptoms have lasted five years. They are a puffy face and head, with a dry, rough skin, pallor, feeble pulse of sixty, subnormal temperature, constipation, and mental lethargy.

POISONING BY THREE DRACHMS OF TINCTURE OF BELLADONNA.

DR. J. B. AYER was called to see a girl twelve and a half years old, who had taken three drachms of tincture of belladonna by mistake. It was given at 9.30 P. M., and the mistake was discovered at 10.25. Although the patient seemed comfortable, feeling only dryness of the throat, her mother kept vomiting her with salt water and ipecac for twenty minutes.

At 11, Dr Ayer found the pupils widely dilated, not reacting to light. There was dryness of the fauces; the skin was dry and red; the pulse 135, very feeble and irregular.

Passing an œsophageal tube, he filled the stomach and washed it out by siphoning, and then gave an enema of a gill of strong coffee.

By this time the cerebral symptoms had appeared. The patient was in a state of mild delirium. The eyes could not accommodate; she could not tell whether objects were near or distant, and it seemed to her that there was a white sheet dancing up and down in front of her. Nitrate of pilocarpine ($\frac{1}{4}$ grain subcutaneously), had a decided effect in diminishing the dryness of the throat and skin. Strong coffee was given at frequent intervals, but was not retained.

The cerebral symptoms were less marked at the end of a couple of hours; the pulse was less rapid, 120, and much stronger, and she wished to sleep, but was, however, kept awake without much difficulty. At 7 A.M., the pupils were still enlarged, and did not react to light. Three days later they were still dilated, but reacted readily.

Recovering from the effects of the poison, she found herself cured of the nausea and diarrhœa for which it had, by mistake, been taken. The over-dose had no effect whatever upon a habit of nocturnal incontinence of urine.

This tincture of belladonna was prepared two years ago, (U. S. P. 1870), and the amount taken contained twenty-two grains of belladonna leaf. There is a very great difference in the price and strength of belladonna leaves, and it is impossible to say whether the amount taken would have yielded one-

twentieth or one-tenth of a grain of atropia. The therapeutic and toxic character of preparations of belladonna do not depend *entirely* upon the amount of atropia by analysis from them. Most of the belladonna was *probably* absorbed in the course of fifty-five minutes, as the stomach was nearly empty at the time.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.

S. J. MIXTER, SECRETARY.

APRIL 1st, 1885. DR. C. B. PORTER, presiding.

DR. G. L. WALTON showed

A CASE OF CONCUSSION FOLLOWED BY PARALYSES POINTING TO HÆMORRHAGE INTO THE FISSURE OF ROLANDO.[1]

He also took the opportunity for demonstrating the use of Broca's Flexible Square, and the measurements were shown, on the skull, by which the course of Rolando's Fissure can be marked out with sufficient accuracy to determine the point for operation, when advisable.

IN the remarks on the communication, Dr. H. P. BOWDITCH stated that he thought some authorities, EXNO, for example, did not believe that the centres of movement of the arm and leg were so clearly and sharply defined as Ferrier would make one believe, and that they certainly overlapped each other, if nothing more. He called attention to the experiments of Göltz, of washing away portions of the brain with a stream of water when it was still found that the animal, notably dogs, were able to perform the ordinary reflex movements of walking, but the more complicated ones, as holding a bone in their paws, they were unable to accomplish.

DR. PUTNAM asked whether the depth of the lesion was determinable? He cited a case where the symptoms pointed to the brachial plexus as the seat of the injury, but where two days later an attack supervened which showed conclusively the central origin of the paralysis.

In answer to Dr. Bullard's question regarding the diagnosis of the seat of hæmorrhage as being cortical rather than into the internal capsule, Dr. Walton said that the nature of the injury was an important factor in the diagnosis. The symptoms might certainly be the same in case of hæmorrhage into the internal capsule, but such lesion, he considered, rarely followed trauma, excepting where previous disease of the arteries favored it, whereas it was not at all unlikely that a cortical hæmorrhage under the seat of injury should follow such a blow as the patient received.

In answer to Dr. Bowditch, Dr. Walton said that pathological observations are of necessity too inaccurate to establish exact boundaries, but they corroborate Ferrier's experiments sufficiently to justify us in assuming that the region about the fissure of Rolando is devoted to motion, and in operating under the guidance of this assumption. The fact may further be regarded as established, that the upper part of this region presides over the movements of the opposite arm and leg, the middle part over movements of the opposite arm. and the lower part over those of the opposite side of the face and tongue.

[1] See page 3 of the Journal.

DR. A. T. CABOT reported a case of

AMPUTATION AT THE SHOULDER JOINT FOR SARCOMA OF THE ARM.

The patient is a girl of twenty, tolerably well nourished, though of rather sallow complexion. She entered the Massachusetts General Hospital, February 16th, 1885, with the following history:— Between two and three years ago, she first discovered a small lump upon the inner side of the right forearm. Fifteen months ago, having reached the size of a hen's egg, it was removed. Eleven weeks later another small tumor appeared beneath the skin upon the inner side of the same arm, just above the elbow. When first noticed it was freely movable beneath the skin; it soon, however, became fixed and increased rapidly in size, but was never accompanied by very severe pain. Some weeks before she entered the Hospital a prominent lobe of the tumor ulcerated, and from this there were one or two hæmorrhages of moderate amount. The tumor at the time of admission, was about the size of a child's head, composed of several large lobes which surrounded the arm, and were at one point ulcerated and sloughing.

While awaiting operation in the hospital there was another slight hæmorrhage, which was easily checked by direct pressure. The arm was amputated on February 21st.

To avoid any loss of blood, which might have been serious in her anæmic condition, the arm was raised to empty it by gravitation, and a rubber tube was applied tightly about the shoulder. The limb was then removed by a circular amputation about two inches below the joint, and after securing the vessels the head of the bone was easily shelled out.

This method was adopted for two reasons; first, in order that the upper end of the humerus might afford the turniquet a sure hold until the vessels were secured, and secondly to at once get rid of the heavy sloughing arm which would have been difficult to manipulate during disarticulation.

To test the efficacy of the rubber tube turniquet about the shoulder, I reapplied it through the axilla and over the spine of the scapula and acromial end of the clavicle while disarticulating, and found that after removal of the head of the bone it still thoroughly controlled the circulation. Whether it would remain in place on a thick muscular shoulder or could be dislodged by movements of the patient, I could not judge.

The after history of this case has been uninterruptedly good. Under a dry absorbent antiseptic dressing the wound quickly healed by first intention without fever or disturbance of any kind.

DR. O. K. NEWELL read a translation from Mickalicz, on the value of the transfusion of blood and infusion of salt solution in acute anæmia.

DR. BOWDITCH said that it might be of greater use than the writer seemed to think, in case of poisoning by coal gas, in helping eliminate the poison from the system.

DR. BUCK spoke of the difficulty of finding the saphenous vein in two cases where he had seen this operation attempted. It was urged by Cohnheim that the central end of the artery was the best place from which to make the infusion, as the risk of overloading the heart was very much less, as well as for the accidental admixture of a large bubble of air.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON SURGERY.

STATED meeting, December 14th, 1885.

THE INDICATIONS FOR LAPAROTOMY IN PENETRATING STAB AND SHOT WOUNDS OF THE ABDOMEN.

After a brief introduction by the chairman, Dr. Stephen Smith, the discussion was opened by Dr. Joseph D. Bryant, who said that he who unconditionally asserted that any operation or method of procedure should be resorted to in all cases, even though it were a measure accepted by the profession generally, took a position that required, in justice to the profession and the patient, that all operators should be competent and well equipped for its performance. Especially was conservatism necessary in the advocacy of an operation, the propriety of which, as yet, was spoken of by many with doubt commingled with dread. But a short time had elapsed since the late Prof. James R. Wood had in this hall opposed laparotomy in the cases under consideration in what were generally recognized at that time as sound practical principles; and though marked advancement in all surgical procedures had taken place since then, a sufficient period had not yet elapsed, nor were the members of the profession well enough informed on the details of the entire operation for any one to proclaim boldly that laparotomy should be performed in all cases. Few indeed were the hospitals in the city of New York which could immediately after the accident offer the recognized theoretical, and many of the practical facilities necessary to despatch and cleanliness in operating; not to mention other circumstances bearing on the success of the operation. How much less properly prepared for the performance of laparotomy would the unfortunate patient find the members composing the great mass of the profession?

There were three questions which he thought it well to consider, namely: 1. Should laparotomy be performed in any case? 2. Should it be performed in all cases? 3. When contemplated, should it be done immediately after the accident? In regard to the first, he went on to say that it could not be denied that laparotomy in connection with various abdominal growths was a fully established operation, and the results attending the invasion of the abdominal cavity by numerous operators both at home and abroad plainly attested the expediency of the measure in connection with such growths. There was no proof, so far as he knew, that the peritoneum of the male was not as tolerant of manipulations as that of the female. The excellent success of Billroth and many others, so far as immediate results were concerned, from operations on the stomach, pylorus, gall-bladder, spleen, kidneys, etc., of both sexes, fully showed that intolerence of the peritoneum to manipulations could not be considered a rational objection to the operation of laparotomy for penetrating abdominal wounds. These operations showed also that neither could the length of time required nor the extent of raw surfaces resulting in this variety of laparotomy be urged as objections to the procedure.

Among the practical elements which at the present time entered into a case of laparotomy for penetrating wounds, but which did not exist, or at all events, exert an equal force, in laparotomy for other common causes might be mentioned the following:

(1) A doubt whether the abdominal viscera were injured. This doubt could exert but little influence, since the signs and symptoms of visceral penetration were as pronounced as those relating to other conditions in which laparotomy was deemed advisable. Moreover, an exploratory laparotomy would enable the operator to settle the question of penetration.

(2) Existing shock. This element was almost unlimited to those cases of laparotomy which were to be done for penetrating wounds. The shock was due either to loss of blood, to injury done the parts, or to both combined. He believed it to be an established fact that when severe shock followed immediately after the injury, it was due in the great majority of cases to loss of blood; and if this were the case, the indication was to check the hæmorrhage at once. An exploratory laparotomy would decide this question.

(3) Unfavorable surroundings of the patient. This element, like the second, was limited to laparotomies for penetrating wounds. It included the surroundings of the patient at the time of the injury, the removal to his home or to a hospital, and the absence of proper preparations for operating in accordance with the best recognized methods of procedure in such cases. It would be impossible to entirely avoid these contingencies; but their dangers could be greatly lessened by caution in moving the patient, by taking him to a suitable hospital, instead of his own home, and by increased familiarity on the part of the profession with all the details pertaining to the operation of laparotomy under the circumstances.

(4) Unskilled operators. By this he said he meant that the surgeon in charge of the case might not have had his attention forcibly drawn to the details of the operation which was recognized as having an important bearing on the prognosis of such cases. More particularly would he find himself in this position if he had previously looked on the operation with a disfavor bred of prejudice, instead of the result of patient toil and observation. This element could be entirely overcome if the members of the profession would but devote an ordinary amount of attention to the matter.

(5) Greater exposure of the abdominal cavity and its contents. The great care necessary in order to find out and to remove from the abdominal cavity all the blood and estravasated intestinal contents, to check hæmorrhage and also to detect all the points of injury, required that the intestines and the omentum should be thoroughly examined by a preconceived method, rather than by the rough handling associated with illogical haste.

(6) Existence of hæmorrhage. In visceral perforation intra-abdominal hæmorrhage was necessarily a constant feature. The vessels of the omentum and of the intestines, especially the former, bled with a pertinacity which was unusual in those of other portions of the body, owing, it was thought, to the walls of the vessels being loosely supported by the surrounding tissues, also to the fact that they seemed to possess in a much less degree the inherent attributes which ordinarily enabled the natural forces of a vessel to check hæmorrhage, namely: contraction and retraction. The suspicion of the existence of much intra-abdominal hæmorrhage was enough to indicate the making, at least, of an exploratory incision, by which means its existence could be positively diagnosticated; when, if necessary, the incision could be extended, bleeding points checked, and blood-clots removed.

(7) Extravasation of intestinal contents. This was

a part of the history of penetrating abdominal wounds, and constituted an occurrence which was most to be dreaded by the surgeon.

DR. GROSS asserted that no case had ever been known to recover in which fœcal matter existed in the abdominal cavity; therefore, fœcal extravasation was the strongest of the indications for laparotomy — offering, as it did, the only means of recovery.

(8) The greater difficulty of cleansing the abdominal cavity. If blood and intestinal contents had been generally diffused, the cleansing of the abdominal cavity was more tedious and difficult, and also of more importance than in laparotomy for other causes, but the thorough performance of this duty, at least so far as the intestinal contents were concerned, appeared to be the only means of saving the patient's life. As to blood, no one could tell the amount that might remain, and yet recovery occur.

In Dr. Bryant's opinion, laparotomy was a justifiable operation, but it was not to be attempted, even in so-called favorable cases, unless the operator could avail himself of many of the recognized means of procedure necessary to control the shock of the operation, and was sufficiently familiar with its steps to accomplish the work with accuracy and despatch.

Leaving the second interrogatory, should laparotomy be performed in all cases, to be discussed by others, he passed on to the third. When contemplated, should laparotomy be done immediately after the accident? Assuming all things to be equal, he thought that it should be done at once, or, at least, as soon as the necessary preparations required to insure a fair prospect of success could be made. There should first be an exploratory incision, followed, if the condition of affairs warranted it, by the actual laparotomy. In the former, the incision was made in the median line, so situated and of sufficient length to expose to view the probable seat of the internal injury. The surgeon could then, in the great majority of instances, determine if penetration of a viscus had taken place, and if hæmorrhage or intestinal extravasation existed. If the patient was in danger from immediate hæmorrhage, the blood in the abdominal cavity could be seen through the incision.

Does the exploratory incision expose the patient to unusual danger? The large number of successful laparotomies, both in this country and abroad, seemed to him to argue this question in the negative, and if this was true, he said, all that was possible was gained, while but little could be lost from the exploratory incision.

DR. J. W. WRIGHT said that he was not prepared to take the ground that all cases of penetrating wounds of the abdomen were to be treated by laparotomy. As regards gunshot wounds, it would be found that the large or small size of the missile, as well as the velocity of the latter, made a great difference in the severity of the injury. For example, he did not believe that the twenty-two calibre bullet, or the ordinary bullet of about twenty grains' weight, behind which there was but about five grains of powder, was calculated to do much mischief. As a rule, such a bullet lodged in the abdominal walls, but even if it did penetrate the cavity, and pass through a knuckle of intestine, the opening made by it was so small that an erosion of the mucous membrane was caused, which would be sufficient to prevent the extravasation of fœcal matter, while the hæmorrhage would be but trifling. If, then, he were called to such a case, and there were no symptoms specially calling for laparotomy, he certainly would not perform the operation. But if, on the other hand, he was called to a case in which the injury had been inflicted by what is known as an "express charge" — a forty calibre bullet, weighing two hundred and seventy grains, with one hundred and ten grains of powder behind it — he would expect to find abundant indications for its performance. Even in the absence of symptoms, he would consider the case one for immediate laparotomy, for he would feel very sure that if such a missile got into the abdominal cavity at all, it would cut and tear everything that came in its way.

In stab wounds, he said he would not perform laparotomy in many cases, even if he knew that the wound was a penetrating one, or even if the omentum was protruding. In this connection he mentioned the case of a drunken sailor, who stabbed himself in the abdomen, and when a portion of the omentum protruded through the wound, caught hold of it, and dragged it still further out. Yet the man recovered perfectly, and that without being laid up for an hour. On the very day that he received the injury, he went to sea, and in the course of a week, the protruding omentum sloughed off, after which he had no further trouble. He also mentioned another somewhat similar case at Bellevue Hospital.

As to the matter of diagnosis, it was difficult to say in every case, whether the peritoneum was wounded or not. In many instances, there was well-marked shock, simply from the force of the blow, particularly if this was in the neighborhood of the epigastrium. If the shock was extreme and protracted, however, it was probable that the abdominal cavity had been penetrated. In the second place, the occurrence of meteorism indicated damage to the viscua. Thirdly, the protrusion of the gut through the wound proved nothing as to whether the gut itself had been injured or not. This was shown, however, by the escape of the intestinal contents. He thought, therefore, that we should be careful how we state that laparotomy is called for in every case.

DR. R. F. WEIR said that he did not feel in a position to say that penetrating stab wounds of the abdomen were necessarily accompanied with injury of the intestines or abdominal viscua. Unless, in any case, there were symptoms indicating the presence of such complications, the surgeon had only to watch the patient carefully. In regard to gunshot wounds, there was a different state of affairs, and for his own part, he had a somewhat greater respect for the capacity for injury of the small pistol ball than Dr. Wright felt, since he had known them to penetrate the abdominal cavity, and do a considerable amount of mischief. As a rule, one of the indications was to explore the wound under any circumstances, and he thought that statistics clearly proved that every gunshot wound of the abdomen, at short range, should be carefully examined, in order to see whether or not it penetrated the cavity.

The question of hæmorrhage always came up in connection with the existence of shock, and it was often impossible to determine off hand in any instance, whether the patient was suffering from the shock of the injury or of extravasation, or from the shock of hæmorrhage. He had learned from the experience of two sad cases that delay might prove fatal, (although if the shock was not due to hæmorrhage, the chances

of success with laparotomy would be greater after it had passed off), and, therefore, he agreed with Dr. Bryant that it was best to make a small exploratory incision in every case where it was impossible to decide whether the shock was due to hæmorrhage or not. He did not agree with Dr. Bryant, however, that the small opening would show whether there was much bleeding or not. The blood naturally gravitated toward the lower part of the abdominal cavity, and, therefore, it was often necessary to pass in a sponge on a stick in order to find out the existence of hæmorrhage. Dr. Wright had stated that a small bullet might pass through the intestine without causing extravasation of fæces, or otherwise doing harm, but the very reasons which would make such a wound of less severity, would also be the ones why a laparotomy would be of less severity under the circumstances. For himself, he would proceed to perform laparotomy if the exploratory incision showed that the intestines were wounded, for even if there was no extravasation of fæces, there would almost certainly be an escape of gas into the peritoneal cavity.

DR. A. C. POST thought that in regard to incised wounds, it made a great difference in what part of the abdomen the stab was inflicted. If in the region of the stomach and liver, there was less danger of hæmorrhage than if the wound was situated in the region of the intestines. Again, if it was still lower down, it might be below the peritoneum altogether, especially if the bladder was distended at the time. In this connection, he related a case in which a stab wound of the lower part of the abdomen penetrated the bladder, and was followed by a gush of urine, and said that in a case of this kind, the safety of the patient, no doubt, was due to the large size of the wound, which gave free drainage, and prevented the retention of the urine in the tissues. A large and direct opening would also have much the same effect as regards extravasated fæces. When there was fæcal extravasation, however, he thought that laparotomy should always be performed and the abdominal cavity thoroughly cleansed.

DR. W. M. POLK said that he had had no experience with laparotomy for penetrating wounds, but so far as danger was concerned, the results obtained, both at home and abroad, showed that the exploratory incision was quite a simple affair, comparatively free from danger. It seemed to him, however, that a simple incision, such as those who confined their attention to pelvic surgery frequently had to make, would scarcely be sufficient in the class of cases now under discussion. The gynæcologist generally knows about what condition of things he might expect to find, and if a large tumor was present, he swept his hand around it, but did not mix his hands much with the intestines. Even in the case of the most extensive growths, the intestines were very little disturbed. This, then, was the point: If a limited exploration were made, there was comparatively little risk, but if it was necessary to introduce the hand, and feel around among the intestines, a great deal was added to the risk. Within the last two or three years, he had seen this strikingly illustrated in this city, in Tait's and other similar operations. Formerly, when there were marked adhesions, the intestines were freely handled, and sometimes laid upon the abdomen, and the result was that a fatal result frequently followed. Within the last eighteen months, however, in this same class of cases, the results had been very much more favorable, and this was owing to a different method of procedure. A much smaller incision was now used, and the adhesions were quickly torn away by the hands, without regard to hæmorrhage, because the latter soon ceased, and a drainage tube was introduced to remove the blood. Instead of the operation covering an hour or an hour and a half, as before, it now took only twenty or twenty-five minutes. The whole question of danger, therefore, as it seemed to him, would depend on the amount of handling of the viscera required in any given case. So far as the simple opening of the peritoneum was concerned, he thought it was as safe as sewing up the cervix uteri, and attended with really less danger than the opening of the pleural cavity.

DR. W. G. WYLIE thought that the principal cause of shock in the cases under consideration was hæmorrhage. The dangers in Tait's and other similar operations, to which Dr. Polk had referred, he believed to have been due, not so much to handling of the intestines, as to exposure to septic influences from the atmosphere, sponges, etc. According to his observation, the large majority of the deaths were due to septic infection. He would have no hesitation in opening the peritoneum in any case where the patient's life was in question. There was very little danger of increasing shock thereby, and if the shock was very marked, there was every reason to believe that severe hæmorrhage was taking place, so that the prompt performance of laparotomy was urgently demanded under the circumstances. After performing operations in the abdominal cavity, he not infrequently washed out the latter with a solution of bichloride of mercury, one to ten thousand, following this with the injection of simple hot water.

NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting, December 1, 1885. The President, W. R. BIRDSALL, M.D., in the chair.

DR. WILLIAM A. HAMMOND read a paper on

UNILATERAL HALLUCINATIONS.

ABSTRACT.

The fact that hallucinations of sight and of hearing might be unilateral, that is, discerned by one visual or auditory centre only, had long been known, though it had not even at this day attracted the degree of attention which Dr. Hammond thought it deserved. Several authors had considered the matter from a more or less philosophical standpoint, and had brought forward interesting cases in support of their views. The first reference to the fact that hallucinations might be one-sided, which had come under his notice, was made by Calmet, it being a case of hallucination coming from the left ear. Baillarger cited two cases of hallucinations of hearing occurring in but one ear. Other writers who had contributed to the subject, cited by Dr. Hammond, were Schroeder van der Kolk, Alexander Robertson, E. Regis, Dumontpallier. Erroneous impressions of different character, occurring on either side, had received attention at the Medical Congress at Rouen, in 1883.

Dr. Hammond then gave the histories of several cases of unilateral hallucinations which had come under his own observation. The first was that of a gentleman in good general health, who contracted the illusion that the ticking of a clock on the mantle-piece

consisted of articulate words; after a time it sounded like human speech, and appeared to give commands, such as not to eat of soup, not to drink wine, etc. It was learned that these illusions came only through the left ear, and never through the right; but hearing in other respects was not the least impaired in either ear. The patient did not allow himself to be deceived into the idea of accepting these commands as realities, yet he was influenced by them in his actions. This case and the one next mentioned were referred to in Dr. Hammond's work on insanity.

Case II. A young lady, of good mental development, but of delicate physical organization, was for several months almost constantly troubled with apparitions of various kinds of faces. A few weeks before they first appeared she had looked at engravings of Greek and Roman masks, which had made a strong impression upon her. If she closed either eye, about half of the faces would disappear, and if she closed both eyes, all would disappear, but would return again in a little while, although less distinctly. By imitating the experiment of Sir David Brewster, pressing on the outside of the globe of either eye so as to produce temporary strabismus, the patient could make any face appear double which had been visible for several minutes. There was no impairment of vision of any other kind, and no abnormal ophthalmoscopical appearances. The peculiar features of this case were that the hallucinating images were divided between the two eyes, part being seen in the one and part in the other, showing, therefore, the distinctness and divisibility of the action of the two visual centres, and the fact that the stimulus of a strong light was necessary in order that they should be developed.

Case III. A young man received a blow just above the left ear. A few weeks subsequently, while engaged as a salesman, he saw a large black cat sitting on the floor immediately before him. He had no doubt of the reality of the occurrence until he walked toward the animal, when it receded as far as it was when he first saw it. After this the cat seemed to follow him wherever he went, but his sense of touch was never deceived. The image was larger and most distinct in the evening, and during the paroxysms of pain at the seat of the injury on the head, which returned several times a day; he discovered, on shutting the eyes alternately, that the vision occurred only on the side corresponding to the injury. There were no abnormal ophthalmoscopical appearances, nor of vision in other respects than mentioned. That there was serious brain lesion, involving probably the left optic thalamus, Dr. Hammond said he had no doubt. He had also been of opinion that there had been fracture of the inner table of the skull at the point at which the blow had been received, and he proposed trephining, which was not consented to.

Case IV. A lady about fifty years of age became the subject of most malignant persecutions through anonymous letters, the sender of which she did not know. While thinking of who the person could be that sent the anonymous letters, she happened to look out of the bay window, and saw a man and woman standing in the opening. For a moment she did not doubt the reality of the appearance, but when she arose, they gradually faded from view. Afterward they reappeared several times in the month, and finally ceased to appear altogether. The interesting feature of the case was that the man was always seen with the right eye, and the woman with the left; if she closed the right eye, she saw only the woman, but if she closed the left eye, she would see only the man. The vision could be brought on by lying down with the head low. Dr. Hammond thought nothing could be more confirmatory of the idea of the independent action of the two visual centres than such hallucinations; indeed, he thought they were strong evidence of the duality of the brain. None of the cases which Dr. Hammond had cited went to support the view that unilateral hallucinations were due to disease or derangement of the organ of special sense involved. Indeed, it was difficult to conceive what connection could exist between disease of the eyes or ears and an hallucination existing in the corresponding side, for if such disease caused a unilateral hallucination, we should expect bilateral hallucinations to be the result of disease of both eyes or ears. Dr. Hammond thought hallucinations were produced by disease or disorder of the central organ of perception, probably of the optic thalamus, and that such erroneous sensorial impressions, when limited to one side, were evidence that the visual, auditory, or other sensorial centre of the corresponding side was the starting point.

Discussion on Dr. Hammond's Paper.

Dr. Leonard Weber related a case which he thought would interest Dr. Hammond, as going to support the view which he seemed to entertain, that unilateral hallucinations were not associated with disease of the special sense concerned, but with an affection of central origin. The man came under his observation in 1879, at which time he was thirty-seven years of age, strong, healthy, very active in business, but, in consequence of domestic trouble and mental strain, he began to lose sleep, was sensitive to strong light, loud noises, etc., and from 1879 to 1881 was subject to hallucinations connected with the left ear. On going to bed he would be unable to sleep for two or three hours because of whispering noises, growing louder and louder, heard in the left ear, and of two kinds, one soothing, and another demandatory. A careful examination by himself and by a specialist in diseases of the ear, failed to reveal anything wrong connected with the auditory apparatus. When the patient's circumstances changed, and he was enabled to lead a peaceful life, the hallucinations disappeared, and had not returned.

Dr. E. C. Spitzka had not heard the entire paper, but, being familiar with the author's views regarding the function of the optic thalamus, he was somewhat surprised that he had not tried to harmonize his observed facts with the anatomical and physiological facts which had been incontestably established during the past decade. Lewes, upon whom Dr. Hammond probably rested chiefly for support of his views, expressed his ideas regarding the functions of the optic thalamus as many as twenty-five years ago, and what he wrote was mere guess-work. If he had been supported in part by recent accurate methods of research, such as the atrophy and other methods, it was a mere coincidence. Dr. Spitzka said his own views regarding hallucinations were directly opposed to those of Dr. Hammond. He believed that hallucinations had their seat in the cortex, and not in the optic thalamus, or any of the lower ganglia. The optic tract and thalamus might have undergone secondary atrophy, following enucleation of both eyeballs, yet the person would be capable of having hallucinations, showing that

hallucinations had not their seat in the optic thalamus. The case cited by Dr. Hammond, in which, during her hallucination, the patient saw the figure of a man and woman, showed the exercise of mental qualities which could have their seat nowhere else than in the cerebral cortex. Dr. Hammond had asked whether he did not believe a hallucination to be something which had been previously registered in the memory, and which was projected outward. He would reply that, without quibbling with terms, that was precisely what he meant by an hallucination.

DR. M. A. STARR related the facts in a case reported by Vetter, in which a patient, having right hemianopsia, imagined that she saw people sitting at her right side, which was the blind field of vision. By a process of exclusion, it was shown that the lesion could not have existed in the optic thalamus, but must have existed in the occipital lobe. Dr. Starr thought that in all probability the source of the hallucination, in this case, was cortical irritation. Certainly, in a great many cases, cortical irritation would produce hallucinations; this was observable in meningitis in which the optic thalamus was not implicated.

DR. W. M. LESZYNSKY recalled the case of a woman in an insane asylum, fifty years ago, suffering from mania, who was in the habit of sitting hours at a time with the left ear inclined toward a table, sending, she said, and receiving telegraphic communications. She did not receive the telegraphic communications with the right ear, which she said was only for general use. Hearing seemed to be normal, perhaps that in the left ear was a little more acute than that in the right ear.

DR. SACHS referred to a case of hemiplegia, with tumors in the optic thalamus, reported by Minot, and asked Dr. Spitzka whether he could imagine an excitation of the cerebral cortex giving rise to an image of hallucination, the revival of such image not being due to an antecedent peripheral irritation.

DR. L. J. CORNING asked why hallucinations which might be produced by impressions coming from the peripheral nerves, might not also be produced by an irritation at any point in that peripheral tract, as in the thalamus. We would all admit that the higher forms of conception took place in the cerebral cortex.

DR. C. L. DANA would like to hear the subject discussed which Dr. Hammond probably wished to bring before the Society, namely, the duality of the brain. So far as the mechanism of hallucinations was concerned, he thought all would agree with Dr. Spitzka that it was essentially in the cerebral cortex, but the exciting cause might be a peripheral irritation, acting upon the psychopathic centres.

As to the duality of the brain, he thought there were many more arguments against the proposition than for it, but the subject was one of great reach, and could hardly be discussed at this hour. The cases of hallucination cited did not, it seemed to him, prove much because only a small part of the psychical mechanism was involved. On the other hand, the experiments of Dumont Paré proved little, because hypnotized subjects could be led to do almost anything by slight suggestion. But pathological observations, the results of hemi-atrophies, of tumors on one side of the brain, studies regarding language, etc., all went to show that the two cerebral hemispheres had certain distinct functions, and that there were not two halves of the brain, each having about the same function.

DR. CHARLES HEITZMANN said that although he was not a specialist in this department, he had given considerable study to it, and he had received the impression that neurologists were not entirely clear in their ideas concerning the seat of irritation which caused hallucinations. Let the physiological fact be remembered that an impression upon our senses can be brought forward at any time in the shape of a protracted sensation, or hallucination. Thus, a peculiar sound might be heard which was merely the image of a real sound, and constituted an hallucination. Everything which we have learned is deposited in the brain, especially in the gray substance. In the case of the black cat, could the man have had an hallucination of a black cat if he had never seen a black cat? I doubt it. Wherever the centre for the image of the black cat may be, if any portion of the nerve tract, leading from the retina to that centre, be disturbed, it will be likely to excite that centre, and the image of the black cat will be revived. The special point of interest connected with the cases related was that they were unilateral. He asked if that might not be explained on the supposition that the irritation, being upon one side, led to the centre for the given image upon that side only.

DR. SPITZKA said, with regard to the duality of the mind, that there could be little difference of opinion regarding the following facts: first, that the two cerebral hemispheres were alike in structure, the variations being no greater than in other symmetrical organs, if allowance be made for a higher type of development; the hemispheres were united by a symmetrical commissure; they had corresponding peripheral tracts; they had about the same distribution of retinal fields; post-mortem examinations on the insane went to prove that the hemispheres were symmetrical; one hemisphere might be practically destroyed, and yet the individual retain power to exercise the several faculties of the mind, as reasoning, memory, judgment, etc., not, however, that there would be no paralysis or other symptom. But it was a different matter entirely when it was suggested that unilateral hallucinations could exist when the corresponding hemisphere was perfectly healthy.

DR. HAMMOND, in closing the discussion, said it was not his object in reading the paper to discuss specially the function of the optic thalamus. He might say, however, that he believed a person could have hallucinations without an optic thalamus at all, provided he had a cortex; but he believed also, that he could have hallucinations without any cortex, provided he had an optic thalamus. In the former case, the hallucinations would be due to revival of past impressions; in the latter case, they would be original, having nothing to do with former associations. A man without an optic thalamus could have an idea of a cat in the abstract, but he could not have an hallucination of a particular cat unless he had an optic thalamus. He believed that ideation resided in the cortex. With regard to the duality of the mind, many arguments might be brought forward, but time would not permit.

The Society adjourned.

— M. Laborde, at a recent meeting of the Société d'Anthropologie, exhibited some arrows which had been poisoned with curare a hundred years ago. He had wounded a few guinea-pigs with them, and the results were as powerful and as deadly as though the poison had been fresh.

Recent Literature.

Applied Medical Chemistry. A Manual for Students and Practitioners of Medicine. By LAWRENCE WOLFF, M.D., Demonstrator of Chemistry, Jefferson Medical College, etc. Philadelphia: P. Blakiston, Son & Co. 1885.

The object of this book is to present in a concise form the practical applications of the principles of chemistry, so far as these are of interest to the student and practitioner of medicine. Part I. it devoted to apparatus and manipulations; then follow in order sections devoted to the chemistry of poisons, physiological chemistry, the analysis of excretions and concretions, and sanitary chemistry; the latter comprising the chemical investigations of air, water, and food. The treatment of the four important branches of chemistry, just mentioned, in a book of the size of this one (160 pages) must necessarily be very superficial. We cannot recommend the work as a book of reference for practitioners; it may prove useful to the author's students in following his demonstrations. Some parts of the book are very carelessly written.

Aids to Gynæcology. By ALFRED S. GUBB, L.R.C.P., M.R.C.S. New York and London: G. P. Putnam's Sons. 1885.

This little paper-covered book of seventy-four pages is one of the so-called "Student's Aid Series." As the name implies, it is intended to give very briefly the salient points of the principal diseases which come under the head of Gynæcology, and it fairly well attains its object. For a quick review of the field just before an examination, it might be very useful, but there its usefulness would end. Many statements are made about which there might be some doubt, but that is excusable, for anything like a critical examination of different opinions on any given point, would be impossible in so brief a work, nor does it seem to us desirable that a book intended exclusively for students, should attempt to cover the field too thoroughly. A definite ground-work of fact should be given them, which later may be modified by study and experience. As a book of suggestions for students, this does very well.

Manual of the Diseases of Women. By CHARLES H. MAY, M.D. Philadelphia: Lea Brothers & Co. 1885.

This book, though much more pretentious in title and in appearance, has really, or should have a similar aim and scope as the preceding. The author says it lays no claim to originality, but is a compilation. The work seems to have been well and judiciously done. Our only doubt would be whether such a book would meet any very marked want. It is rather too full for the busy student to run over hastily to refresh his memory. It is certainly not full enough for a text-book, and a practitioner who wished to consult some book to help him in an obscure or difficult case, would hardly be satisfied with the brief *résumé* he would find here. Still it may meet a want among students, and it can be recommended as a safe, clear, and systematic treatise of gynæcology. It is well arranged, the etiology, pathology, differential diagnosis, symptoms, and treatment of the various diseases being briefly, but clearly indicated.

Medical and Surgical Journal.

THURSDAY, JANUARY 7, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

TUBERCULOSIS OF BONE.

WHEN Shakespeare represents Richard, Duke of Gloster, contemplating his deformity, the following are the words used:

> "I, that am curtailed of this fair proportion,
> Cheated of feature by dissembling Nature,
> Deformed, unfinished, sent before my time
> Into this breathing world, scarce half made up."

The royal humpback doubtless attributed his misfortune to some wretch's curse, to a fairy's displeasure, or to the influence of an unlucky star; or, if he were anything of a rationalist, he might have thought himself a victim of a freak of Nature, of imperfect growth, or injured by some prenatal maternal blight.

If the modern prototype of Gloster is anxious to know the cause of his affliction, the man of science takes him to a microscope, and shows in him a field of pretty red cells a granular mass, and in the centre of this a cluster of blue elongated specks, called by courtesy rods, and tells him that this is his enemy; that it is this foe who has blighted his youth, handicapped his manhood, and perhaps been the originating cause in the nexus of events which has twisted his character, and given occasion for the series of acts to culminate in the disaster of his Bosworth Field.

To this height of apparent absurdity, we are led by the votaries of this new cult, who from the hidden arcana of their researches — from the region of cultures and moulds — issue edicts and bulls, which now are ruling the world, shaping legislation, and awaking the fashion of pilgrimages to the shrines of the popular high priests.

It would hardly be surprising if the conservative and sensible layman should prefer the legends of the old nurses to this modern absurdity. It must, however, be frankly admitted that the theories advanced are supported, as a rule, by well-grounded facts, and, if we leave out the expressions of over-zealous enthusiasts, are so presented as to leave the onus of the discussion on the doubter.

No attempt will be made here to maintain the relation of the tubercle bacillus to tuberculosis; it will, nevertheless, be assumed that the microbe is the chief

efficient cause, when acting on proper soil, for the pathological changes known as tuberculosis.

The relation of tuberculosis to caries of bone, is, however, a matter which has awakened a good deal of interest in the European surgical world, and is the subject named for a discussion in the next German Congress of Surgeons. Volkmann,[1] at the last Surgical Congress, boldly states as an aphorism that "Everything which has hitherto been classed as caries of bone — spina ventosa, scrofulous inflammation of the joint or bone, tumor albus, strumous disease of the bone — belongs, with but few exceptions, to true tuberculosis."

This tuberculosis originates either in the bone, or in the synovial membrane, but the former is much more common in children. It begins with the formation of a circumscribed tuberculous focus in the epiphysis, which, as a rule, remains comparatively small. The diffuse form of caseous infiltration is less common. The affection, at first, is not properly a joint affection, but one of the bone, and may remain extra articular if the suppuration extends outside, instead of bursting into the joint. In children there is in the spongy bone a special tendency for the localization of the disease, the tuberculous tissue being inclined to undergo caseous degeneration and form a mass, separated from the rest of the bone by a line of demarcation, containing granulation cells, which, though studded with miliary tubercles on the innermost layers, protects the neighboring bone from infection; so that a direct extension in the bone from a caseous sequestrum is exceptional.

There may, however, be two or more tubercular foci in the same epiphysis. The olecranon and the iliac portion of the acetabulum are known to be common places for these foci to be formed in, but the matter of favorite localities for the affection has not been thoroughly studied as yet.

Primary tubercular disease of the synovial membrane is more common in adults, particularly in old people, and is seen most commonly in the knee. Tubercular synovitis may be accompanied, by development of granulations, forming the so-called fungous disease of the joint; or these may be absent, and a torbid suppuration of the joint may be present — a form occasionally seen in old persons and of unfavorable prognosis. The tubercles may be deposited in a cluster, or they may be widely disseminated on the synovial membrane.

Non-tubercular affections of the joint only exceptionally become tubercular, as far as the matter is, at present, known. Tubercular disease of the joints, whether primarily synovial or osseous, does not necessarily involve suppuration, but may develop into the form of the so-called *caries sicca*. Tubercular eruptions in the synovial membrane may occasion simply an extensive serous effusion, classed as Hydrop's tuberculosus, but this form is rare. Tuberculosis of bone, not in the neighborhood of joints, is to be found in the phalanges, the metacarpals, and metatarsals, exceptionally in the ulna and radius, tibia and femur, but is almost exclusively confined to young childhood. Tuberculous suppuration of the orbital plate of the upper jaw is also seen in young children, tuberculous caries of the ribs is not uncommon, but the most common of tuberculous affections of bone not involving joints is caries of the spine. Tuberculosis of bone never occurs in the long bones of adults.

Tuberculous affections of joints, bones, skin, and glands, apparently, are less liable to give rise to general tuberculosis than tuberculosis of the lungs or intestines. Tuberculosis does not recur in the wound after complete removal, as by amputation for tuberculous disease of joints, even if the patient may be suffering from another tuberculous disease, as phthisis; but wounds after operations for bone tuberculosis, may undergo tuberculous infection if the tuberculous matter has not been thoroughly removed during the operation. Local recurrence, therefore, after operation, is not to be attributed to a vice of the constitution so much as to a lack of thoroughness on the part of the operator. In operating on joint affections of this sort, it is, therefore, essential that not only the affected portion of the bone should be removed, but that the whole of the diseased synovial membrane should be carefully dissected off. Curetting the synovial membrane is said not to be sufficiently thorough, but in osseous tissues, owing to their greater resistance, all tuberculous matter can be removed by the curette.

Sinuses remaining for a long time, indicate the presence of tuberculous infection, and demand, for a speedy cure, either dissection, thorough cauterization with the actual cautery, or packing the parts with iodoform after enlarging the opening.

Thoroughness in detail is the secret of success in this branch of surgery, as in all others; but locally removing the disease, though it may prevent local extension, does not prevent reappearance elsewhere. A spontaneous arrest of the disease under conservative treatment, is, however, not at all uncommon, particularly among children.

Therefore, even though the modern theory of the origin of tuberculosis, and of the tuberculous nature of the caries be entirely accepted, the riddle seems as far from solution as ever; for the important query remains unanswered as to the cause for individual surrender, and for individual resistance to the bacillus; why certain races, certain stocks, are doomed from the first to a decimation in the warfare with the fearful invisible enemy, while others escape the same dangers, and bloom under the same conditions.

To state the necessity of suitable soil for the development of the bacillus is to reopen the question, and we are still obliged to answer our questioning deformed layman by telling him that he was born under an unfavorable star, or that a fairy had cursed him at his birth.

In the meantime, however, we can enjoy the slight satisfaction of telling him that if he place his children

[1] Centralblatt f. Chirurgie, No. 24, 1885.

in a dwelling clean, swept, garnished, free from microbes, and keep them, during their growing years, under such conditions that only filtered air can reach them, only aseptic clothes can cover them; if their food be ideally perfect, and their associates and belongings scientifically immaculate, they are certain to grow up and encounter the bruises of childhood without fear of the deformities which crippled him.

PHYSIOLOGICAL AND THERAPEUTIC EFFECTS OF COCAINE.

DRS. RIGOLET and Victor Pradel have recently presented to the Société de Thérapeutique of Paris two exhaustive theses on the physiological and therapeutic properties of hydrochlorate of cocaine, based on experimental studies.

These are Rigolet's conclusions:[1]

(1) Hydrochlorate of cocaine acts on the periphery of the nerves, abolishing momentarily the sensibility of the mucous membrane and skin; (2) The anæsthetic effect thus produced is essentially local; (3) In frogs this salt exercises an active effect on the heart, slowing its beatings, and finally arresting it in systole; (4) It has a manifest vaso-constrictive action, and produces, at first a fall, then a rise in the blood pressure; (5) Hydrochlorate of cocaine has no effect on the secretions, except that of the submaxillary gland whose salivary secretion is augmented by it; (6) In frogs, it diminishes the respiratory movements; in the higher animals it accelerates the movements and increases their amplitude when injected into the veins; (7) Cocaine muriate produces hyperthermia in the dog; (8) It is eliminated by the urine; (9) It retards fermentations.

In toxic dose, cocaine acts on the nervous centres, and exaggerates the excito-motor power of the spinal cord. It tetanizes the muscles. With regard to the therapeutic employment: cocaine renders great service in all operations where it is not necessary to produce general anæsthesia. It is in ophthalmic surgery that its advantages are most conspicuous. Its anæsthetic effects are less marked in eyes affected with inflammation than in those exempt from all phlegmasia; it will not render much service as an analgesic to inflamed eyes. This salt may be utilized as a narcotic in ophthalmology. It seems also to give good results in gastralgia, in sciatica, and in other neuralgic affections. In the treatment of morphio-mania cocaine may be substituted for morphia. Subcutaneous injections of chlorhydrate of cocaine seem to be quite harmless. The solutions most in use contain one, two and five per cent.: the weaker solutions are quite safe for internal administration. The combination of cocaine with ether and chloroform does not seem markedly to increase the analgesic effects of the former.

Pradel's conclusions are as follows:

(1) Hydrochlorate of cocaine has a very remarkable excito-motor action, which can be observed in all animals, but which takes on a different character according to the animal under experimentation. In the monkey it causes violent convulsions, to produce which three centigrammes of cocaine per kilogram of the weight of the animal are required; (2) Certain therapeutic agents have a marked influence on these convulsions. Choral prevents, while ether retards them. Morphia aggravates these convulsions, and the association of these two alkaloids, even in non-toxic doses, rapidly produces the death of the animal; (3) Cocaine is a hyperthermic medicament and the elevation of temperature is proportional to the dose employed. This hyperthermia takes place independently of all convulsion. Choral prevents this elevation of temperature. Morphia administered along with cocaine, causes a fall in the temperature which is quite notable. Antipyrine has no action on the hyperthermia produced by cocaine; (4) Cocaine anæsthetizes locally the mucous membranes; it has no action on the healthy and unabraded integument. Cocaine enters into the category of anæsthetic depressors of sensibility and exciters of motility. It resembles in this respect strychnine; (5) In hypodermic injections cocaine, in doses of one centigram produces a marked analgesia, varying according to the subjects; (6) Cocaine has a real action on the fermentations which it retards, though less than creasote and phenic acid.

With regard to therapeutical effects of this alkaloid, M. Pradel deduces the following conclusions from clinical observations:

(1) All the mucous membranes are anæsthetized by cocaine; the quantity necessary to obtain an analgesic effect varying with different organs; (2) Several drops of a two per cent. solution suffice to render the superficial part of the eye analgesic; (3) To obtain the same effect on the iris, it is necessary to make successive instillations every five minutes for the twenty minutes preceding the operation; (4) The analgesic action of cocaine on the inflamed eye is disputable; (5) Cocaine does not seem to produce mydriasis, and when such a result is experienced, it is because the cocaine employed is not pure; (6) The urethral mucosa is rendered analgesic by cocaine; solutions of two per cent. suffice for this; (7) Under the influence of this analgesia spasms and contractures disappear, and catheterism is rendered easier; (8) Cocaine does not prevent the supervention of "catheter fever;" (9) To obtain analgesia of the mucous membrane of the ear and nose, fifteen to twenty per cent. solutions are necessary; (10) For the mouth and throat, solutions of different strengths are required; ten to fifteen per cent. for the palate, five to ten per cent. for the fauces, two to three per cent. for the floor of the mouth; (11) Sprays of cocaine have produced suffocation; (12) Painting with cocaine is useful in dysphagia due to ulceration of the pharynx; (13) For the anus, strong solutions are necessary; five to ten per cent.; (14) Solutions of two per cent. are sufficient for the vulvo-vaginal mucosa in cases of vaginismus; (15) The neck of the womb is made analgesic by solutions of twenty

[1] Bull. de la Soc. de Thér. Science, October 28, 1885.

per cent.; (16) With solutions less strong (four per cent.) a moderate analgesia is obtained which mitigates the suffering of child-bearing; (17) Cocaine acts on the skin denuded of epidermis as it acts on the mucous membranes. This effect has been utilized in fissures of the nipple; (18) The analgesia produced by hypodermic injections of cocaine may be useful in certain operations, such as those for phymosis, fissure and hæmorrhoids; (19) Cocaine calms, for a certain time, vomiting of hysterical nature. The employment of cocaine ought to be carefully watched in neuropathic persons: (20) In therapeutic doses cocaine is unattended with any injurious effects; (21) When cocaine is administered subcutaneously, pains must be taken to ascertain the particular susceptibility of the patient to this alkaloid, and knowing that some persons are peculiarly affected by it, the physician should feel his way carefully.

A BOSTON POLYCLINIC.

ONE of the latest phases of medical education in America has been the rapid development in the large cities of the east of some form of Polyclinic, where the abundant material that swarms to their hospitals and dispensaries could be utilized for clinical instruction, and where the graduate in medicine could find some of the advantages of practical teaching that he had formerly sought abroad.

The Polyclinic in New York is already well known and the number of doctors who come to its exercises shows how real is the demand for such an institution; also in Philadelphia and Baltimore other organizations of the same kind have been established. In Boston the growth of this method of instruction has been so quiet that its existence has been less known, yet, starting in the summer of 1879, there were last year about fifty persons in attendance. Each year the increasing proportion of those availing themselves of these advantages have been graduates, and the rest advanced students of medicine. During the first year these courses were given under the title of "Clinical Courses of Instruction in Medicine." But with an increase in the teaching force and in the numbers attending a more compact organization was found necessary, which has been brought about by uniting these instructors together as the Boston Polyclinic.

In the beginning, two objects were kept in mind:— to provide instruction which would be mostly clinical and practical, and to limit the number in each class so that every member could examine the cases for himself, and this plan has been carefully adhered to.

Last summer nineteen courses were offered with a maximum number of ten in the largest class. But in many others the number was limited to four or five and for the last two years the work has been carried on during the winter as well as the summer months. There can be no doubt that this form of medical instruction is a most desirable one, for, whilst avoiding the evil of adding another to our overburdened list of institutions that give degrees, it increases the amount of available clinical instruction, of which there cannot be too much, and of which there has been in former years generally far too little. By competition it sharpens and stimulates instructors. The subject taught, the instructors and the instructed must all profit by such a system. The teachers in Boston have charge of clinics at the City and Massachusetts Hospitals, the Eye and Ear Infirmary, and Boston Dispensary, so that a large and varied material is at their disposal. In this work there has been no spirit of antagonism to existing institutions, but rather an effort to supplement and stimulate them by offering more abundant opportunities, and thus draw men to this city who would otherwise seek this instruction elsewhere. In the JOURNAL of April 13th, 1882, we took occasion to refer favorably to these courses of instruction in discussing "extra-mural" teaching, and since then they have been improved in efficiency and scope.

Those who have attended the Vienna Polyclinic will remember with pleasure the facilities there offered for instruction and study, and will see in the development of the Polyclinic on this side of the ocean an extension of its methods and its aims.

Many doctors after a few years of practice would like to devote some weeks to the study of a department of medicine for which they previously had no opportunity, provided it could be done without too great a sacrifice of time and money; but formerly this instruction could only be had abroad. For this reason the advantages which are now offered to Americans in the larger cities of the country have an especial value, for they are now able to see a large number of cases under the instruction of men who have made themselves familiar with what is best in the methods and teachings of the foreign schools during a stay abroad, and have learned by experience what is useful and applicable in the diagnosis and management of disease as presenting itself to us at home.

MEDICAL NOTES.

— The *Medical Record* comments on the chances of success in the medical profession as compared with those in business life, and quotes Sir James Paget, who has traced the course in life of one thousand medical students, taken at random from an English college. About five per cent. of them failed utterly, while nearly ten per cent. more left the profession without giving it a fair trial; one-half made a fair living, six and a half per cent. achieved considerable success, and two and three-tenths became eminent. Of the whole number who began, less than two-thirds achieved any kind of success. Whether Sir James Paget's figures will apply to the United States, it is impossible to say definitely. Our contemporary remarks that the opportunities for a successful career are naturally much greater here, and if it were not for the fact that competition is twice as active, a much larger percentage of successes would be scored. As it is, it thinks that the probabilities are, that of the four or five thousand

medical students who are annually graduated by our schools, over one-third of them fail or fall by the way.

BOSTON.

— The Obstetrical Society of Boston, celebrated the completion of its twenty-fifth year on Tuesday last, by an elaborate dinner at the Parker House.

— A few social gatherings of the profession have been arranged for at the rooms of the Boston Medical Library Association. The first will occur on January 15, at which Mr. Cushing, the ethnologist, will give an address on "Medical Practice as it Exists among the Zuñi Indians."

— The Boston City Hospital has secured for the room devoted to the treatment of out-patients with diseases of the nervous system, a new and unusually complete system of electrical apparatus.

— The Children's Hospital has received, during the past year, legacies to the amount of over $25,000. The managers hope to be able, before long, to undertake the erection of a new wing, which is much needed.

— Three children at Quincy Point, near Boston, are reported as having been poisoned last week by coal-gas from a stove in the room in which they slept. The father was awakened by a peculiar moaning, and removed them at once to the open air, where they were resuscitated.

NEW YORK.

— At a meeting of the New York County Medical Association, held at the Carnegie Laboratory, December 21st, Dr. T. R. Varick exhibited a stone weighing seven ounces and four scruples, Troy weight, which he removed from the bladder of a lad fourteen years of age, on the 9th of December, by the bi-lateral operation. It measured six and three-quarters inches in circumference longitudinally, and five and one-half inches transversely. He had had it sawed open, and the section showed a nucleus of uric acid, surrounded successively by layers of urate of ammonia, triple phosphates, and urate of ammonia again. It had been six years since the first symptoms of bladder trouble were noted.

In operating, he had commenced with the left lateral incision, but, finding that this was insufficient, he made a right lateral incision also, so that the external wound was somewhat of a V shape. On account of the large size of the stone, he had found great difficulty in extracting it, and had, in fact, to follow the curve of the pelvis, and deliver it very much as if it had been a fœtal head. There was considerable shock from the operation, but the patient rallied speedily, and up to the present time (the twelfth day), he had progressed without any unfavorable symptom. The urine had been found to contain a large amount of mucus, some pus, and a small quantity of albumen.

Dr. Varick said that, according to Sir Henry Thompson and other authorities at the present day, the rule was, that in all cases where the stone weighed anything over three ounces, the high, or supra-pubic operation was to be adopted; but in this case, on account of the elasticity of the soft parts, and the small size of the prostate, from the patient's age, he had decided to disregard this. After the operation, he had applied hot water to the raw surfaces, and the wound was healing rapidly, in fact, too rapidly, since, on account of the condition of the bladder, he thought it better that the urine should find exit through the perineum for some time. The boy was certainly doing perfectly well up to the present, but whether there would remain any resulting disease of the kidneys or not he could not say.

Dr. J. W. S. Gouley said that this case afforded a beautiful illustration of the extent to which young subjects will bear bladder irritation. He thought that the boy would get well, and that he would not have any pyo-nephritis. If the patient had been an old man in such a case as this, there would undoubtedly have been a fatal termination, as there would have resulted disease of the ureters, followed by that of the kidneys. The good result here was due to the practical absence of the prostate. Personally, he said he would not have dared to extract such a stone as this entire, but would have broken it up into four or five pieces. There were instruments capable of doing this, and if it could not be accomplished otherwise, it might first be perforated in several places. This was a much safer procedure, and Malgaigne had called it lithotriptic lithotomy. Dr. Gouley had given it the name of lithoclastic lithotomy, which he thought was better. He was glad that Dr. Varick had refused to perform the supra-pubic operation, and he said that he would take this opportunity to offer his protest against this procedure. The high operation was a dangerous one, the mortality from it being very great, and among the complications which were to be feared in connection with it were the protrusion of the intestines from the wound, and the infiltration of urine. This might be the present fashion; but it was one that would pass away, as it had already done three times before.

— At the last meeting of the Medical Society of the County of New York, held December 28th, Dr. John C. Peters, chairman, reported the conclusions of the Committee on Hygiene upon the conferences lately held with the Taxpayers' Association in regard to the proposed great Quaker Bridge dam in connection with the Croton water system. He said that, owing to the urgent need of an increase in the water supply, the committee had joined in the petition for the construction of the Sodom dam, which would insure double the present supply to the city in two or three years, at a cost of $1,250,000. At the same time, the committee did not feel disposed to stand in the way of the Quaker Bridge dam project, as it had the earnest endorsement of engineers. There was uncertainty, however, about how long it would take to build it, and what it would cost, and the city could not wait upon such an uncertainty. When completed, it would hold water enough for 4,000,000 people, pouring out 400,000,000 gallons a day. With such an outflow, he did not believe the water could become stagnant or impure, as the oppo-

nents of the plan urged, while it would certainly catch the Croton overflow, and stop the present enormous waste. After some discussion, in which one of the speakers said that if the Brooklyn Bridge had been constructed of solid masonry, it would be a small affair compared with the proposed structure, and that of nine huge dams, none so large as this, four had broken through, the report of the committee was adopted.

At the conclusion of a recently published communication on this subject, in which he points out a number of objections to the Quaker Bridge dam, Mr. James Renwick, the architect, says: "There are so many difficulties, therefore, to be overcome, so many unknown quantities also in the problem, it seems to me that it would be unwise, as well as improvident, to attempt it; and particularly as the cost will, in my opinion, be at least three times the $4,000,000 or $5,000,000 estimated. On the other hand, a sufficient supply can be got by building comparatively small dams above the present dam at a low expense. Why, therefore, should we try to do what is barely possible, when, by the latter means, we have a certainty, and freedom from danger, for a much less cost than that of the Quaker Bridge dam? I may also state that we have had one earthquake, and that, therefore, we may have another. Should this happen, and a crack be made in the dam, it might destroy the whole structure, and the wave created by letting so enormous a body of water into the Hudson, would sweep the river from end to end."

— The first cremation in Buffalo was successfully made December 27th, at the new temple of the cremation company, and the statistics of the test were as follows: Weight of body, 98 pounds; weight of ashes, $3\frac{7}{16}$ pounds; time consumed in the cremation, one hour and five minutes; estimated highest degree of heat in the retort, 2,332° Fahrenheit. The most successful incineration thus far made at the Mount Olivet Crematory was accomplished December 30th, when the time consumed was one hour and thirteen minutes, or about two hours shorter than that of any previous cremation there.

— The reports thus far received show a gratifying increase over last year in the collection made in the churches on Hospital Sunday, this result being no doubt principally due to the fine weather of the last Sunday of 1885.

Correspondence.

ELECTRICITY AS A THERAPEUTIC AGENT IN GYNÆCOLOGY.

BERKELEY, Cal., Dec. 22, 1885.

MR. EDITOR, — I am heartily glad to see this matter brought prominently before the profession by the paper of Dr. Paul F. Mundé,[1] and the discussion which followed it, because I know that gynæcologists generally fail to appreciate the value of this agent, and greatly overestimate the trouble and annoyance of its application.

Exactly why electricity should prove so beneficial in such opposite conditions as amenorrhœa and menorrhagia, it is impossible to say, except in a general way, that either condition is produced by or productive of deficient or perverted nervous force. But in either condition, (*of course* excluding all cases where there is acute, or even subacute inflammation) I *know* that the galvanic current, *properly applied*, will more generally bring relief than any other form of treatment.

My aims, and rules of procedure have been few and simple: —

First, never to produce more than a very slight pain, in some cases a slightly hot tingling, in others "a little unwell pain," as the patients express it. Broadly, one may say that this should be accomplished by from three to six or eight, or at the most ten cells of a "Smart" battery. But the batteries vary greatly, and each physician must become thoroughly acquainted with his own instrument. Nor do I believe that the galvanometer, as urged by Dr. Birdsall, can take the place of the patient's sensations. I use a cup and stem insulated electrode at the cervix uteri, (*positive* pole, to lessen the tendency to stick to the mucous membrane), and interrupt the current with a common sponge electrode over the pubes. This — while bringing the uterus, and if desired, the ovaries and tubes well within the circuit — does not involve any undressing of the patient, or at most only the removal of the drawers, if worn close.

And second, to give the *tonic* effect of the current, but *never to exhaust the nerves* by a too prolonged application. This I consider a matter of the very first importance. My applications vary from three to five minutes, and never (in such cases) exceed the latter limit. Since the adoption of this rule, my results have been far more satisfactory.

As a minor, but still important advantage, I may point out that neither Dr. Garrigues nor any one else, need give up the use of electricity in these cases "because it takes up too much time." Very truly yours,

ALEXANDER R. BECKER, M.D.

[1] Read before the New York Academy of Medicine, November 5, 1885, Journal, November 19th.

HUMANIZED VIRUS.

JANUARY 4, 1885.

MR. EDITOR, — I am very glad to see by Dr. Chas. V. Chapin's letter in your issue of December 31st ult., that the stock of long humanized virus, unmodified by renewal from the cow for over eighty-five years, is still maintained at Providence: for a comparison between the vaccinia induced by this stock and by that of heifer transmitted cow-pox virus is thus made easily practicable. This difference can readily be seen by the simple experiment of vaccinating an infant upon one arm with the former, and upon the other with the latter stock. To observe the difference in constitutional effect, it would of course be necessary to devote a separate child to each, preferably two children in the same house. The different arms should be inspected and compared daily throughout the entire course of the disease, as should also the resulting crusts and scars. If the Providence stock have the pedigree claimed for it, it will produce a disease which bears to that described by the first writers on vaccination, a resemblance which may be compared to that of a faded-out photograph of a person taken by some rural artist, to the person himself. The vesicle will be small, involving the skin but very superficially, and liable to spontaneous rupture. The areola will be slight, transient, and appear at the beginning of the eighth or end of the seventh day. Except in very rare instances, no febrile reaction will occur. The crust will be small, thin, and quite generally wanting in umbilication; will fall on the fourteenth day, and finally the resulting scar will be extremely superficial and barely discernible.

On the other hand, the results of vaccination with heifer transmitted cow-pox virus will be papulation of points of insertion at the end of the third or beginning of fourth day; first development of vesicle at end of fifth day; commencement of areola at latter end of ninth or beginning of tenth day; decline of areola twelfth to fourteenth day; decided febrile reaction coincident with the areola; vesicle large,

and not liable to spontaneous rupture; the crust adherent till the twenty-first to thirty-second day, umbilicated, nearly as large as the vesicle, of a dark color, and as the morbid process involves the true skin to a very considerable extent, the lower portion of the crust will consist of a slough composed of the dermal tissue. The scar left behind will be deep, clear, and well marked, not foveolate or pitted, but characterized by cicatricial rays or bands, radiating from the centre.

Virus from the animal, when dried upon points, is not so readily soluble as humanized virus, and of course it is necessary that it be perfectly dissolved before it is applied to the arm. From the want of appreciation of this fact, and of the slight extra care which is thus made necessary, some have been led into the very erroneous opinion that it is difficult to make the virus take. The fact is that it will produce vaccinia in precisely the same percentage of primary vaccinations as the humanized, and in a far greater, nearly double, in revaccinations. Vaccinations with animal virus are also free from the troublesome complications sometimes attending those from the humanized. I wish it to be understood always that I speak of animal virus worthy of the name, taken from proper vesicles at the proper time. It would be well if the fact could be generally appreciated that the object of vaccination is not to produce a disease of as mild and trivial a character as possible, but one that will protect from variola. The literature of post-vaccinal variola shows the protective power of long humanized virus. I have yet to learn of a case of that disease following successful vaccination with the animal virus. I have revaccinated this season a number of children of fifteen years of age who were vaccinated with the animal virus in their infancy, and in none of them have I been able to produce any effect.

Yours respectfully,

S. C. MARTIN, M.D.

27 DUDLEY ST., Roxbury.

REPORTED MORTALITY FOR THE WEEK ENDING DECEMBER 26, 1885.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 1,682: under five years of age 564; principal infectious diseases (small-pox, measles, diphtheria, and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 288, consumption 249, lung diseases 239, diphtheria and croup 146, typhoid fever 43, diarrhœal diseases 26, scarlet fever 25, whooping-cough 21, malarial fever 12, puerperal fever four, cerebro-spinal meningitis four, erysipelas three, measles two, small-pox two. From scarlet fever, New York 12, Philadelphia three, Cincinnati two, Lynn, Springfield, Holyoke and Chelsea one each. From whooping-cough, New York 16, Charleston three, New Bedford and Baltimore one each. From malarial fever, New York eight, Baltimore two, Philadelphia and Nashville one each. From cerebro-spinal meningitis, New York three, Northampton one. From puerperal fever, New York two, Baltimore and Charleston one each. From erysipelas, New York three. From small-pox, New York two. From measles, New York two.

Cases reported in Boston: scarlet fever 31, diphtheria 22, and typhoid fever seven.

In 107 cities and towns of Massachusetts, with a population of 1,207,964 (population of the State 1,941,465), the total death-rate for the week was 15.63 against 15.29 and 16.26 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,266,446, for the week ending December 12th the death-rate was 20.3. Deaths reported 3,464: infants under one year of age 793; acute diseases of the respiratory organs (London) 443, whooping-cough 111, measles 109, scarlet fever 42, fever 32, diarrhœa 24, diphtheria 29, small-pox (Bristol and Liverpool, two each, London one), five.

Birkenhead 20.7; Birmingham 19.6; Hull 20.7; Leeds 21.6; Leicester 16.9; Liverpool 24.6; London 18.8; Manchester 24.1; Nottingham 22.7; Sheffield 22.5; Sunderland 17.5.

In Edinburgh 21.7; Glasgow 28.8; Dublin 31.0.

The meteorological record for week ending December 26th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Dec. 26, 1885.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 26, 1885, TO DECEMBER 31, 1885.

MADDOX, THOS. J. C., assistant surgeon and first lieutenant. Killed December 19, 1885, in affair with Apache Indians, near the White House, New Mexico.

IVES, F. J., assistant surgeon. Ordered to report to commanding officer, District of New Mexico, for duty in the field. S. O. 127, Department Platte, December 23, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE TWO WEEKS ENDING DECEMBER 26, 1885.

PURVIANCE, GEORGE, surgeon. To proceed to Chicago, Ill., as inspector, December 23, 1885.

GUITERAS, JOHN, passed assistant surgeon. To proceed to Saint Louis, Mo., for duty, December 23, 1885. Granted leave of absence for seven days, December 26, 1885.

URQUHART, F. M., passed assistant surgeon. To proceed to Charleston, South Carolina, for temporary duty, December 23, 1885.

BRATTON, W. D., assistant surgeon. Granted leave of absence for twenty-two days, December 22, 1885.

MCINTOSH, W. B., assistant surgeon. Granted leave of absence for fourteen days, December 22, 1885.

DEATHS.

Died in South Scituate, Mass., December 29, 1885, Nathan Pike Brownell, M.D., M.M.S.S.

In Worcester, Mass., December 30, 1885, Rufus Woodward, M.D., M.M.S.S., aged sixty-six years.

OBITUARY.

JOHN ORNE GREEN, M.D.

Dr. John O. Green, of Lowell, whose death in his eighty-seventh year, was recorded in our recent necrology of the Massachusetts Medical Society as occurring on December 23d last, was born in Malden in 1799, and was the son of Rev. Aaron and Eunice (Orne) Green; he went to school in Medford, entered Harvard College in 1813, graduating in 1817; he taught school for a time both in Andover and in Castine, Me.; he took his M.D. degree at the Harvard Medical School in 1822, and settled in East Chelmsford — which afterwards became Lowell — in the same year.

Here Dr. Green continued to live, with the exception of a visit to Europe in 1847, the rest of his long and useful life. He grew up with the place and became identified with many of its most important civic and social interests. He was for more than fifty years vice-president of the Lowell Institution for Savings, and latterly its president; for thirteen years a member of the School Committee, at one time president of the Lowell Lyceum, of the Lowell Bank, of the Old Resident's Association, in which he took a deep interest: he also served the city as an alderman, and was health commissioner. He was for many years senior warden of the church of St. Anne. He was president of the Middlesex District Medical Society, became a councillor of the Massachusetts Medical Society in 1841, and its orator in 1847.

Dr. Green was married three times. His first wife was a daughter of Dr. Calvin Thomas, a successful and much respected practitioner, of Tyngsborough, Mass.; his second wife was Miss Slater, of Rhode Island; and his third wife, who died a few years ago, Miss McBurney, of Boston. He leaves two sons, one of whom, Dr. J. Orne Green, is a member of the Massachusetts Medical Society and a resident of Boston.

SOCIETY NOTICES.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The annual meeting of the Society will be held at the Medical Library Rooms, No. 19 Boylston Place, on Thursday, January 14th, at 4 o'clock, P.M. The Annual Address will be given by the President, Dr. H. O. Marcy. Subject: "The Perineum of the Female: its Anatomy and Function." Illustrations upon the screen by the oxy-hydrogen light. All members are urged to be present.

H. J. HARRIMAN, *Secretary.*

BOSTON MEDICAL LIBRARY ASSOCIATION. — The Medical Library, 19 Boylston Place, is hereafter to be open on Tuesdays and Fridays, from seven to ten in the evening, instead of closing every day at six, as hitherto.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, January 13, at 7.45 o'clock. Papers: I. Dr. E. O. Otis, "Random Notes on some Health Resorts." II. Dr. H. F. Vickery, "Enlarged Cervical Glands." III. Dr. E. B. Lane, "Two Cases of Cerebral Tumor, with autopsy." F. KNIGHT, M.D., *Chairman.*

ALBERT N. BLODGETT, *Secretary.*

SOME CASES OF REFLEX NEUROSIS.[1]

BY G. M. GARLAND, M.D.

The subject of reflex neurosis is one of great interest, and the cases which come under this grouping, exhibit such diversity of phenomena and such excentricities of behavior that they are always fascinating to the observer. The following cases presented themselves at the Carney Hospital, and were there treated during my service in the summer of 1885. They appear to me to be worthy of record.

Case I. M. I. D., merchant, aged fifty-eight, entered the hospital on July 7, 1885. He had been suffering for six weeks with severe supra-orbital neuralgia on the right side. The pain was not continuous, but seized him at frequent intervals every day. Each individual attack was of short duration, but the severity was so great and the patient's dread had become so exaggerated, that he was completely unmanned. He had lost flesh, strength and appetite, and he was nervous to an extreme degree. He had been obliged to give up his business, and he emphasized the apprehension with which he awaited each attack. His tongue was heavily coated and his bowels were constipated.

Upon questioning, it was learned that the patient had had an attack of neuralgia in the same spot three years previous. That attack was of short duration, however, and had never troubled him until it began at this time. He was a man of free habits as regards food and drink. He had always enjoyed good health up to last April, when he had pneumonia, which ran an ordinary course and terminated by complete restoration. His neuralgia began within a few weeks after his recovery from the pneumonia. His face presented a striking contrast between a high color on the cheeks and a zone of waxy pallor round the eyes.

Physical examination revealed the following facts: His heart, lungs and kidneys were sound. There was no tenderness or swelling over the right supra-orbital region. His eyes were normal in appearance, and a later ophthalmoscopic examination by Dr. Derby, revealed merely a slight hypermetropia, which was fully compensated by the glasses which he wore. Nothing abnormal was found in his nostrils or mouth. On opening his mouth, however, to exhibit his teeth, he excited an explosion of pain. The right eye closed, tears ran from it and the lids trembled convulsively. The face flushed and the mouth was drawn toward the painful side. This attack lasted from one-quarter to one-half a minute. The patient then stated that he could produce those attacks by certain movements, which he avoided as much as possible. Chewing his meat at table; drawing his shirt over his head and certain other acts would start the pain. The examination of the ears was next in order, and these were found packed with hardened wax. The right ear was so tightly plugged that it required nearly an hour of syringing before the mass was dislodged. The left ear was cleansed in a few minutes.

The fact that the patient could explode attacks of nervous force at will, by the movement of parts remote from the seat of the pain, led me to the belief that there must be a mechanical cause for the pain, and that I had discovered this cause in the impaction of the right aural canal. Accordingly, I stopped all the quinine and other powerful neuralgic medicines which he had been taking, and gave him simply one-twentieth of a grain of podophyllin before each meal to stimulate his digestive secretions.

The removal of the wax caused no pain or discomfort during the operation, and it was followed by an absolute cessation of the neuralgia for eleven days. Once or twice during these eleven days the patient reported a peculiar sensation over the right side of his forehead. It was not pain, but a sort of twitchy feeling in the skin. This aroused his apprehension again, but he was calmed by encouraging words and was told that time was required to cool the stove after the fire was out. On July 17, he sat and read in the sun for some time, and then experienced a mild attack of neuralgia. The pain differed from his previous attacks in that it was slight, and it persisted for ten or fifteen minutes. The house physician, Mr. Gleason, applied galvanism to his forehead, and this quickly relieved him.

Since that day he has had no other attack of pain. Occasionally he has felt the twitching of the skin, referred to above, and to relieve this, galvanism was applied eight or ten times. After leaving the hospital the patient took a trip to Europe, and has now returned to his business in perfect health.

There are several interesting points in connection with this case. The first is to trace out the nerve circuit between the ear tube and the supra-orbital region. Dr. Hilton shows in his work on "Rest and Pain," that the "upper and anterior part of the external ear and the auditory canal derive their sensibility from the fifth cerebral nerve," so that these portions of the ear are thus included in the sensory circuit with the forehead, temple, face, eyes, nose, teeth and tongue.

The entire posterior surface, and the anterior surface of the pendulous portion, of the ear are supplied by branches from the second cervical nerve.

The presence of wax in the ear tube seems a slight cause for so much distress, and yet if one will put his finger in his ear while making masticatory movements of the lower jaw, he will see that the wall of the canal is thereby moved in a forcible manner. Moreover, the history of a previous attack of neuralgia in the same region would lead one to assume an exaggerated susceptibility of the right supra-orbital nerve. The future history of this nerve will be interesting.

The gradual cooling down of the excited nerve after the removal of the irritating cause was also an extremely interesting phenomenon. For a number of weeks the patient complained of the twitching feeling described above, and such sensations always aroused his apprehensions.

Case II. This case exhibits a reversal of the nerve currents as compared with the previous one.

Miss C. P., aged thirty-two. Entered the hospital June 18, 1885, with the history of a sore mouth since the preceding Friday, together with anorexia and vomiting. The mouth presented the familiar signs of mercurial salivation, with swollen gums and ulcerations. The patient complained of a sharp pain immediately behind the ears. A suitable mouth wash was prescribed and her gums rapidly improved. My term of service beginning in July, the previous treatment was continued until July 13, when my attention was especially attracted by a look of distress on her face,

[1] Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, December 9, 1885.

and by her complaints of a severe ear-ache on the left side which prevented sleep and was wearing out her strength. She said her ear had ached more or less from the time of entering the hospital, but it had grown much worse of late. In examining the ear nothing abnormal could be discovered outside or inside, and there was no tenderness to touch or upon percussion over the mastoid process. Between the anterior edge of the left steno-mastoid muscle and the posterior edge of the ramus of the jaw there was a small spot tender to pressure.

The mouth was next examined. The gums were everywhere healed, except around the left wisdom-tooth. Here the mucous membrane was swollen and pushed forward so as to conceal more than half of the tooth. On lifting this swollen tissue an ulcerated surface was exposed which was very tender to the touch.

A small piece of lint, powdered with iodoform, was inserted between the gum and the tooth, and this constituted the entire treatment. Within two days the gum had receded almost to its natural position. The ear-ache was fast disappearing, and the patient could sleep. On the third day the dressing was omitted by mistake and the pain and sleeplessness returned. The lint was resumed. In two days more the ear-ache was entirely gone, and the patient was discharged well at the end of a week.

CASE III. M. P., aged sixty-eight, entered the hospital June 10, 1885. Had been a sailor and fisherman for years. Ten months ago he contracted a cold and had been troubled with cough and dyspnœa since then. He is frequently awakened suddenly at night and is obliged to sit up gasping for air. During the day he has occasional paroxysms of severe dyspnœa, and his breathing is habitually rapid and labored. His face wears a distressed, weary look. Slight movements cause distress for breath, and he walks about with difficulty. The expectoration is a greenish-yellow, occasionally streaked with blood.

Physical examination revealed sibilant and sonorous râles over both chests, front and back. The inferior boundaries of the lung reached lower than normal, showing emphysematous enlargement. There were no signs of any pulmonary consolidation. Twenty years ago the patient's nose was bent toward the right side by a blow from a ball. Since the beginning of his cold he has noticed that he could not breathe through the right nostril.

From the date of his entrance until July 6th, the patient was treated by various remedies addressed to his cough and to his asthmatic breathing, but no relief had been granted him. On July 6, I made an examination of the patient and found that his right nostril was packed with polyps. These polyps were four in number, large and firm in consistency. After two of them had been removed the patient experienced decided relief from his suffering and slept with comfort. This improvement was still more increased after the removal of the remaining polyps at a later sitting.

All medication directed to his cough was stopped, and he was given some soda powders for his stomach, and an occasional laxative.

The record for July 29, states that the moist râles heard at the previous examination had disappeared. Only a high-pitched sibilant râle could be heard occasionally at the left apex. On violent respiration a few wheezy râles could be heard over the lowest part of the lung in front.

During August, cocaine and glacial acetic acid were applied occasionally to the lower turbinated bones in both nostrils. No other treatment has been employed since then, and within a few days the man reported himself to me in excellent condition. He works about the hospital, goes up and down stairs at will, and breathes with ease. Rarely he has an attack of asthmatic breathing at night.

CASE IV. This was a peculiar case of laryngeal neurosis, which I was unable to trace to any local cause.

M. A. G., aged thirty-nine, unmarried, entered the hospital on September 8th. She has always been a hard worker, but remarkably healthy. Last December after exposure to cold, she began to cough. There was no expectoration then or at any time since. She soon grew somewhat hoarse. This symptom varied at first but finally increased in intensity until she could speak only in a whisper, and this aphonia has persisted up to the time of treatment at the hospital. The cough was of a distressing, barking character, and persisted during all her waking hours at the rate of twelve to eighteen or twenty times per minute. On retiring at night she would lie and cough for an hour or two before she could go to sleep. The cough began by an audible sharp inspiration as if the diaphragm contracted spasmodically, and this was followed by one or two loud expiratory barks. The patient's hands and feet were restless, but exhibited no choreic movements or trembling. Patient says she has lost forty pounds of flesh since she began coughing. Her appetite is poor and she complains of a dull, aching pain at the left side of the back after coughing.

A careful physical examination was made. There was no tenderness or tumefaction about the larynx. The cords were slightly reddened, but were not paralyzed. The throat and pharynx were considerably reddened by the rasping cough. The lungs, heart, kidneys, ovaries and womb were normal. The bowels were constipated but yielded readily to laxatives. Inasmuch as nearly every strong tonic had been tried upon the woman during the months of her affliction without any apparent benefit, it was thought advisible to try the effect of an ice-bag upon the spine. Accordingly on September 10th, the bag was applied for two hours. On the next day and thereafter it was applied for four hours daily.

The hospital record, kept by Mr. Gleason, reports the following progress:

September 13. Patient coughs only when excited or nervous, and then only at long intervals. The cough is no longer loud and barking, but is more like a clearing of the throat. She goes out to walk daily.

September 16. The cough has entirely ceased and patient can use her voice a little. Her appetite and general health are improving.

September 19. The voice is growing louder and clearer every day. No return of the cough.

September 29. Patient is able to talk in an ordinary tone without any hoarseness. Her weight has increased several pounds. Discharged well.

In addition to the ice-bag, the following pill was given three times daily to stimulate the stomach:

℞	Acid. Arsenios	gr. 1-80
	Podophylli	gr. 1-20
	Quin. Sulph.	gr. j
	Strychniæ Sulph.	gr. 1-80
	M	

and the patient also took one teaspoonful of malt after each meal. Considering the large doses of strychnine

and quinine which the woman had previously taken without avail, her improvement at the hospital would seem to be largely due to the influence of the spinal ice-bag.

THE ETIOLOGY OF RACHITIS.[1]

BY H. C. HAVEN, M.D., OF BOSTON.

ALTHOUH we can hardly accept Jenner's statement that "Rachitis is the most common, the most important, and in its effects, the most fatal of the diseases affecting children," as holding true in this country, it is yet sufficiently common to make its prevention of great importance to the public health. It is, typically, a preventible disease — so far as serious results to the individual are concerned — if proper treatment is instituted early enough. It might, probably, be absolutely prevented, if we knew the ultimate causes.

My purpose is to briefly present the statistics I have gathered as to the effect of the commonly-accepted causes of rachitis on its production in this city.

During the past three years, at the West End Dispensary for Children, there were in attendance —

Total number under 7 years	1516
" " of rachitics	75
Percentage of rachitics	4.94
Total number of colored under 7 years	90
" " " " rachitics	38
Percentage of colored rachitics	42.79
Total number of foreign ancestry under 7 years	340
" " " " " rachitics	20
Percentage of rachitis of foreign ancestry	5.88
Total number American ancestry under 7 years	114
" " " " " rachitics	4
Percentage of rachitics of American ancestry	3.50
Number of ancestry unknown	973
" " " " rachitics	10

RACE.

Classifying the rachitics as to race, we find, of the number where it is known: Colored, 38; Foreign, 20; American, 4. Of the 20 rachitics of foreign ancestry, (Provinces included), there were: Portuguese, 3; Italian, 2; Irish, 2; English, 2; French, 1; Nova Scotia, 2; Russian, 1; German, 1; of mixed parentage, both foreign, 4; of mixed parentage, father American, 2; of mixed parentage, mother American, 1.

FEEDING.

Breast alone till 3 months,	308.	11	rachitics or	3.57 pr.ct.
" " " 6 "	295.	7	"	2.37 pr.ct.
" " " 9 "	137.	10	"	7.29 pr.ct.
" " " 12 "	200.	7	"	3.50 pr.ct.
" " over 1 year	60	3	"	5.00 pr.ct.
Breast with other food till 3 months,	74.	5	rachitics or	6 75 pr.ct.
" " " " 6	43.	2	"	4 65 pr ct.
" " " " 9	83.	3	"	3.66 pr.ct.
" " " " 12	477.	9	"	1.04 pr.ct.
" " " " over 1 yr.,	381.	17	rach. or	4.46 pr.ct.
Artificial feeding only,	119.	13	rachitics or	10 85 pr.ct.
Number where food not known,				286
" " " " "			and rachitic,	3

These figures need, of course, a further analysis to make them of much value, but they show, I think, very strongly, that other factors than food are in this series of cases, the original or exciting causes of rickets.

Having noticed the frequency of rachitis among the colored in this series — and I have observed this in the attendance at other dispensaries — let us analyze the feeding of the colored children to see if, so far as they are concerned, the dietetic factor is an important one This was as follows:

Breast without other food till 3 mos.,	18.	7	rachitics, or	38 88 pr.ct.
" " " " 6 "	8.	3	"	37.50 pr.ct.
" " " " 9 "	5.	4	"	80.00 pr.ct.
" " " " 12 "	9.	4	"	44 44 pr.ct.
Breast with other food till 3 mos.,	7.	1	rachitic, or	14 28 pr.ct.
" " " " 6 "	4.	1	"	25 00 pr.ct.
" " " " 9 "	3.	1	"	33.33 pr.ct.
" " " " 12 "	16.	8	"	50.00 pr.ct.
" " " " over 1 yr.,	27.	12	"	44.44 pr.ct.
Artificial feeding only,	16.	6	rachitics, or	37.50 pr.ct.

I recognize the objection, that these statistics are too small to have great weight, but I cannot but think they are sufficiently numerous to show that at least the dietetic factor is not an important one in producing rickets in colored children in Boston; the per cent. of all rachitics among all colored is only a little less than the per cent. of colored rachitics in the artificially fed from birth. And in this series of cases, moreover, many colored children are not counted as rachitic where they only showed slight bone changes. Since December 1, 1884, about the time I began to carefully note any evidence of rickets, the total number in attendance under seven years has been 495 and 52 colored, or 11.5 per cent. Of the 52 colored, twenty-five only were non-rachitic, and 27 rachitic, 51.9. This per cent. even is too small, however, I am very sure, as sometime in the hurry of examination, I have neglected any record, as some of my charts remind me. The only question in regard to the dietetic factor, yet to be spoken of, is this: is the milk of colored mothers, otherwise healthy, as good an article of diet as the milk of the other races? I have no reason to doubt it or affirm it, except that in many of the cases there is no evident failure of nutrition on the part of the child. I hope later to present some analysis of the milk of women nursing rachitic children.

Assuming then, the preponderance of rachitis among the colored race in Boston, and granting the effect of the diet they receive not to be a marked one, at least, as I think we are justified in doing, the question arises as to what other cause may be acting, peculiar not to any racial dyscrasia, but resulting from racial or acquired character and habits; that is, are the quarters of the city in which they live more densely crowded; are the tenements they inhabit more damp and cold or having less sunlight; are their habits of caring for children, especially as to taking them out of doors, different from those of the equally destitute of other nationalities? I can only give my opinion, that all these questions must be answered in the negative. I have no positive information, and hope I may obtain some from others to-night. My experience has been, that the colored are more lavish in expenditure for food and rent than other poor, taken as a class, that in equal ways their table is better equipped and the food better cooked. As for the airing of the children I do not see how they could be taken out *less* than the children of the Irish poor, until after they can walk; after that time I have noticed no difference.

Another question must be considered. Are one or both of the parents less healthy than the average white of same social condition? If they are, this may be considered as a causative influence, transmitted but not acting through direct heredity.

Of the 33 colored rachitics, whose family history is known, both parents *said* to be healthy in 21.

Mother healthy in 4 cases; father dead in 3; 1

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, December 9, 1885.

Bright's, 1 phthisis, 1 rheumatism; in 1 father had cough every winter, well in summer.

Father healthy in 5; mother died in 1 of phthisis; "never strong" in 2; "married at 13" in 1; rheumatic in 1.

In 2 cases there was phthisis in father, and asthma and rheumatism respectively in mother; in 1 father had phthisis and mother died in confinement.

Of 31 rachitic white, whose family history was known, parents said to be healthy in 23.

Of the 8 remaining, in 3 father was healthy, mother had chorea, rheumatism and measles at birth of child respectively.

Mother healthy in 3; father had kidney disease, arsenical poisoning, and "not strong."

Father died of phthisis in 1, with mother not strong; father rheumatic in 1, and mother healthy excepting catarrh which had destroyed septum, specific.

No history of syphilis in any, nor have I seen any rachitic symptoms in a number of confessedly syphilitic children.

In this comparison we see not much difference, but of course the statements of the parents are of comparatively little value; I think, undoubtedly, in this climate the average of health is less in the negro than the white native or immigrant from the north of Europe. How much lower, if any, it is, than that of the immigrant from France or Italy, I have no means of forming an intelligent opinion.

In any case I do not believe there is enough difference to account for the marked preponderance of rickets on the ground of the parent's health, though it may, and undoubtedly does, exert an influence.

What then is the determining cause of this frequency? I see no source of any such cause but what must arise from a peculiar predisposition to this form of disease in the colored. Is this to be referred to any anatomical basis, as for instance, are the arteries of this race larger or wider? I know of no such peculiarity. And again, if the statements made to me by lay observers are true, that the disease is the less common the farther South we go, that would preclude any such hypothesis being entertained. I can find no medical testimony as to its relative frequency. It is stated, however, to be practically unknown in tropical regions. In the writings on African explorations, I have met no notice of such a disease having been noticed among the young, as it would probably have been had it existed. Again, I have been told by lay observers, that the disease is the more frequent and severe, the purer is the African blood, and I have found this to be true in my experience in this city.

The only hypothesis I can suggest to myself to account for the relative frequency of rachitics in the colored race is that as their natural habitation is much farther south than North America, the effect of the climatic conditions, which are recognized as having a causative effect in rachitics, is exaggerated; the purer the African blood the more will the effect be noticed. In other words, there is an inherited necessity for heat and sun which our climate does not satisfy, and rickets results. It is striking in this connection to notice of the white rachitics of a foreign ancestry, the majority are born of parents coming from the south of Europe, where the disease is relatively rare, rather than of parents from England and North Germany, where the disease is rife.

I have presented these facts principally for the purpose and in the hope of eliciting criticism and information which shall enable me the better to make a more thorough study of the subject than I have had the time to do in this sketch.

THE PULMONARY COMPLICATIONS OF TYPHOID FEVER.[1]

BY F. B. HARRINGTON, M.D., BOSTON, MASS.

TYPHOID FEVER COMPLICATED BY CIRCUMSCRIBED PNEUMONIA.

CASE I. Miss G., twenty-five years old, was seen November 10, 1884. The temperature was 104.5°, the pulse 108 and the respiration 32. For five days she had been feeling poorly, and had suffered with headache and nausea. She had a chill and there had been some cough. The tongue was heavily coated. The bowels were regular. On examining the chest a region of dullness was found at the base of the right lung in front. This dullness did not extend above the nipple, and was not marked. In the back it was wanting. Over this area moist râles with slightly prolonged expiratory sounds could be heard. Before the present illness there had been no cough.

The abdomen was slightly tympanitic, and there was slight tenderness in the left iliac region.

November 11th. On the following day the temperature rose to 105.2°. Diarrhœa and some cough.

November 12th. Temperature 104.9°. Diarrhœa and cough.

November 13th. The temperature 104.7°; The cough was slightly increased and the expectoration, previously viscid mucus, became rusty in color. The dullness had increased slightly in intensity though not in area. Fine and coarse râles were abundant and respiration was somewhat bronchial. There was some deafness. For several days the patient seemed to improve and the temperature fell to 99.2° on the 16th.

The rusty expectoration disappeared and the cough became less. The diarrhœa continued. On the 19th she complained of pain in the region of the rectum, and a poultice was applied to a spot of tenderness.

November 22d. A large ischio-rectal abscess was opened by incision, and the rush of pus, and gas showed that it had perforated the rectum.

From this time on the patient gradually grew worse.

November 25th. There was mild delirium, which changed two days later to active delirium. The pulse was gradually becoming weaker. There were abundant râles in both bases behind.

The abscess continued to discharge.

December 2d. The patient died. For two or three days before death there had been an increasing dullness at the bases of both lungs, due to the constantly increasing weakness of the heart.

TYPHOID FEVER WITH HÆMOPTYSIS DURING CONVALESCENCE.

CASE II. Mr. C., of phthisical family, twenty-eight years of age, after the usual preliminary symptoms of typhoid fever, went to bed January 22d, with headache, coated tongue and pain in the right iliac fossa. Diarrhœa began three days later. The patient went through a mild attack of typhoid, and a little over three weeks after the attack the pulse became normal with a slight evening rise.

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, December 9, 1885.

The pulse was now 96 and weak. The temperature never rose above 103°. Considering the moderate temperature and the lack of exhausting symptoms there was very decided prostration. About this time a slight cough developed, but gave little trouble, and the chest was not examined. The improvement in the patient was very slow. At the end of a month the patient sat up for a short time, but was very weak. Two months after he was attacked he was still unable to be about. His cough had become more troublesome. On examining the chest nothing abnormal was found. The pulse was rapid and weak. This was March 17th. Nine days later I was called and found the patient suffering from a profuse hæmorrhage following a fit of coughing. At the left apex I found fine and coarse râles, with dullness and slightly prolonged expiratory murmur. Two weeks later there was a second though less copious hæmorrhage. A month later the patient had so improved that he was able to walk out. The cough continued and still exists, though the man is now about his business.

No disease is so prolific of complication as typhoid fever. No structure of the body escapes entirely. No function is safe. Rupture of muscles, necrosis of bones, abscess of the liver, gangrene of the lungs, loss of sight, aphasia and insanity are but a few of the rarer complications. There are two important causes for this multiplicity of lesions. The first and most important cause is the duration and severity of the pyrexia. The second cause, less demonstrable, is the specific poison of the disease. The continued high fever causes parenchymatous changes in all the organs. Hoffmann [2] found only 56 cases out of 161 autopsies in which the heart muscle was normal or nearly so. The power of the heart is greatly lessened. The circulation is impaired and the nutrition of the parts suffers. The respiratory complications in typhoid fever are numerous. Out of 111 autopsies, from Biermer's clinic, the respiratory apparatus was perfectly healthy in only two instances, according to de Cérenville.[3] Bertz[4] makes a report of 899 cases of typhoid fever from Ziemssen's clinic from 1878 to 1883. Among a large number of complications were the following pulmonary, or intimately associated with pulmonary lesions: —

Hæmorrhagic Infarction,	15
Miliary Tuberculosis,	4

Goldtdammer, in a report of 783 cases occurring at Berlin in 1874, 1875 and 1876,[7] says bronchitis was wanting in only the lightest cases. Hypostatic congestion was found in 40 of those who recovered, and in about one-half of those who died. (There were 130 deaths.)

Lobar pneumonia existed in 11 cases, only one of which recovered. Embolic pneumonia was the cause of death in five cases. There were 13 cases of pleurisy, eight of which died. There was one case of phthisis.

Hoffmann, in a report of 250 autopsies at Basle, says,[8] that bronchial catarrh extending to the finer bronchi almost always accompanied the early intestinal changes. He found: —

Splenization,	35
Lobular pneumonia,	38
Lobar Pneumonia,	18
Pleurisy,	20
Pneumothorax,	1
Hæmorrhagic Infarction,	15
Miliary Tuberculosis,	4

Two of the eighteen cases of lobar pneumonia occurred at the outset of the disease, and will be referred to again.

I have included under the heading "Pulmonary Complication," not only true pulmonary lesion, but also lesion of parts intimately associated, as the bronchi and pleura.

The signs of pulmonary lesion occurring with typhoid fever are usually marked to a greater or less extent. Characteristic expectoration in pneumonia is often wanting. Cough in bronchitis is frequently absent.

When respiratory lesions are epidemic, as might be expected, there is an increased amount of complication with typhoid fever.

Children are found to be more subject to these complications than adults.

As has been already said, bronchitis is rarely wanting in typhoid fever. Liebermeister says: [9] "Catarrh of the smaller bronchi is so frequent in typhoid fever, that a certain diagnostic significance may be attached to its occurrence." It may be so slight as to cause little or no trouble, or may be, and especially in children, a very serious complication.

One of the chief dangers of this bronchitis is that owing to the great general weakness, the secretion may not be thrown off, and atelectasis and broncho-pneumonia may result. Lobular pneumonia is a common occurrence in typhoid fever. A. Weil,[10] owing to the lack of signs, considers it very difficult to differentiate the various forms of consolidation occurring in

[8] Loc. cit.
[9] Ziemssen's Cyclopædia.
[10] Zm. Pathologie und Therapie des Typhus Abdominalis, et cet. Leipzig, 1885.

typhoid fever. He is often unable to determine clinically, whether the consolidation be due to atelectasis, to hypostasis, to lobar or lobular inflammation, or, as often happens, to a combination of these conditions. *Lobular pneumonia* is the most common form of pneumonia occurring in typhoid fever. It rarely begins with a chill, but there is almost always an increase in the temperature.

Lobar (*croupous*) *pneumonia* sometimes occurs during convalescence. At this period it does not differ in any way from an ordinary attack of that disease. There is usually the sharp attack with chill and sudden rise of temperature, dyspnœa, characteristic expectoration and râles.

When croupous pneumonia complicates typhoid fever of the second and third weeks, during the height of the disease, many of the ordinary characteristics are wanting. According to Homolle,[11] the chill is often wanting; there may be no rise in temperature, pain is absent or of short duration, characteristic expectoration and râles are seldom present and the cough is infrequent.

Lobar pneumonia, occurring during the first two weeks of typhoid fever, is the subject of much discussion. It sometimes occurs as a simple complication, at other times there seems to exist a kind of transition form between the two diseases.

Lépine,[12] in his article on "pneumonia," expresses his belief in a form of pneumonia due to the local infection of typhoid fever, in which the pulmonary symptoms are the noticeable ones, and the abdominal symptoms are slight. This he calls pneumo-typhoid.

Hoffmann [13] classes two of the 18 cases of lobar pneumonia which he found as pneumo-typhoid. A short history of one of these cases will illustrate the disease.

Mr. E., twenty-one years of age, began to suffer with headache, September 4th, and had nosebleed. September 13th went to the hospital. The breathing was labored, there were râles in both lungs and dullness and bronchial breathing in the lower right lung. On the 18th the patient died. On autopsy, croupous pneumonia of the right side and infiltration of Peyer's patches and ulceration of the ilium were found. Had the latter lesions been absent, Hoffmann would have considered the case one of pneumonia with typhoid symptoms. [Typhoid pneumonia. Flint.]

Lonquet [14] thinks that there are cases of pneumo-typhoid in which there are no intestinal symptoms, and in which on autopsy no intestinal lesion can be found. He believes that typhoid poison in severe cases makes its entrance through the lungs or has its seat there. E. Wagner,[15] in concluding an article on the subject of pneumo-typhoid, says that, with our present knowledge, it is impossible for us to decide the exact neurological position of the disease. Exact knowledge of the specific germ of the disease will clear this doubt.

Cardiac weakness, so common in typhoid fever, is a direct cause of several of the pulmonary complications. These complications are in no way peculiar to typhoid fever, but may occur in any asthenic fever. They are more common in typhoid fever on account of the duration and intensity of the fever.

Passive congestion of the lungs often occurs as the result of cardiac weakness. This passive congestion may lead to œdema. The passive congestion is most likely to occur in dependent portions of the lungs. It may be unilateral if the patient for any cause has assumed a position upon one side, but when it occurs it is usually bilateral.

This form of congestion has been called hypostatic. When the parts, through œdema, become devoid of air, an appearance resembling the spleen may be seen. This is splenization. Another result of feeble action of the heart is the formation of thrombi. These becoming detached, may cause embolic infarction of the lungs. Emboli may arise from some septic source. Goldtdammer [16] reports five deaths from embolic pneumonia among 783 cases of typhoid fever. The origin of the emboli was in one case the right side of the heart, in another an old perityphlitic abscess, in a third case an abscess of the thigh. The origin in the other cases was not discovered. These emboli may cause gangrene of the lungs, and the pulmonary tissues breaking down, pneumothorax may result. Embolism of the pulmonary artery and instant death is not a rare occurrence.

Like pneumonia, pleurisy in typhoid fever may give little indication of its presence. It occurs frequently, but unless extensive, it is very apt to escape notice. Empyema also occurs, and sometimes independently of pneumothorax. Acute miliary tuberculosis sometimes occurs as a sequel to typhoid fever, but probably not from any direct cause. Phthisis also develops sometimes as a result of the non-absorption of secretions which have not been thrown off during the period of great prostration.

Hæmoptysis, according to Homolle,[17] occurs during typhoid as the result of a hæmorrhagic infarction. It may also occur as a symptom of concurrent phthisis.

The extreme exhaustion of many typhoid cases makes the frequent examination of the patient more difficult. For this reason and from the lack of symptoms many of the above complications undoubtedly exist at times and escape unnoticed. Given a severe case of fever with high temperature and marked abdominal symptoms, diarrhœa, abdominal distension and tenderness with more or less stupor, is the frequent examination of the patient's chest, requiring moving of the patient, necessary or desirable? Flint advises the frequent change of the position of the patient with a view to prevent hypostasis. This certainly is desirable. Patients who have kept a fixed position for a long time will often give signs of hypostasis, which will disappear on assuming another position. If this plan be carried out, there will be no additional fatigue to the patient from the application of the stethoscope. By its use we may learn more of the real strength of the heart than the pulse or the heart sounds could give us, and we may get an earlier warning of the necessity for increased efforts to sustain the heart's action.

Antipyretic measures undoubtedly decrease the frequency and severity of pulmonary complications.

Liebermeister [18] reports concerning 1,743 typhoid patients, about one-half of whom were treated by cold baths, that the number of cases of pulmonary consolidation was reduced from 14.4 per cent. to 10.9 per cent. and that the mortality of these cases was reduced from 54 per cent. to 34 per cent.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY O. F. WADSWORTH, M.D., AND MYLES STANDISH, M.D.

OCULAR AFFECTIONS IN MULTIPLE NEURITIS.

Gnauck [1] gives the results of observation of fifty cases of multiple neuritis in the Charité Hospital. In thirteen patients the external ocular muscles were affected; in nineteen the pupils, in four of these the pupils being immobile.

It is, however, with the disturbances of vision and the ophthalmoscopic condition of the papillæ, that the author has chiefly concerned himself in this paper. Twenty-eight of the fifty patients had disturbance of vision. Eight of these showed nothing but a certain degree of amblyopia. Five had decrease of vision, and contraction of the field. Of the remaining fifteen, some manifested these defects, but all presented alterations in the fundus. The latter changes consisted in total atrophy of the discs, with blindness; partial atrophy, particularly of the temporal halves of the discs; or hyperæmia of the discs and neuritis optica. The defects in the field of vision were, in the majority of instances, concentric, and combined with narrowing of the field for colors; in some, there was a central color scotoma. The peculiarity was noticed that the form of the field sometimes changed greatly within a short time, or the defect even entirely disappeared.

Complete atrophy of the optic discs has been but rarely observed in multiple neuritis. Gnauck gives two cases. A man, of forty-two years, noticed, in February, cloudiness of sight, which increased rapidly. By the end of May, he was totally blind. Only at the beginning of May did other symptoms of disease of the nervous system appear. In June both discs were completely atrophic.

A girl, of twenty-five years, began with ptosis of her right eye. When, after some months, the ptosis had improved, the right eye was nearly blind. It was only at the end of two years that other symptoms of disease manifested themselves. After three years the left eye began to fail, and in the fifth year both discs were wholly atrophic. It is noteworthy that in both these patients the ocular affections were the earliest symptoms of the disease. The same was the case with a third patient, whose history offered also other points of special interest.

A man, of twenty-eight years, suffered from progressive failure of sight for four months before other disturbances of the nervous system appeared. After six months, there was a central scotoma for red and green with no peripheral contraction of the field, precisely the picture of an amblyopia ex abusu, but no abuse of tobacco, alcohol, etc., could be discovered. Two months later, further decrease of central vision with scotoma for blue also. After another two months, sight was decidedly improved, but an atrophic discoloration of the temporal halves of the papillæ was visible. Still another two months, and the central scotoma had vanished, but the palor of the outer halves of the discs remained. As in this case, so generally where there was partial atrophy of the discs, it appeared as a sharply-defined alteration of the outer half, or at least, the inner half was much less affected than the outer.

In three cases, there was marked hyperæmia of the papillæ, or neuritis optica, which left the disc either of normal appearance, or atrophic. Gnauck considers the atrophy of the opticus as often of the greatest importance in making the differential diagnosis between multiple neuritis and neuroses, especially hysteria. He is inclined to believe that the atrophy of the disc, at least when particularly pronounced in the outer half, is due to optic neuritis, either intra, or retro-bulbar.

Uhthoff [2] reports three cases of multiple neuritis, in two of which there was optic neuritis, and in the third an atrophy of the disc, which appeared to have resulted from neuritis. From these cases, and those of Gnauck, he concludes optic neuritis must be of relatively frequent occurrence in multiple neuritis, and this view is strengthened by the fact that he has observed the neuritis in this disease to subside and give place to atrophy in a comparatively short time. It might, therefore, more readily escape discovery.

The manner in which the loss of sight comes on, its character, and the occasional recovery, together with the frequently partial and non-progressive atrophy of the disc, all seem to him to point to an inflammatory origin, rather than to a simple degeneration.

STRETCHING OF THE SUPRA-TROCHLEAR NERVE IN GLAUCOMA.

Brailey [3] read a paper on this subject at a meeting of the British Medical Association. The operation was brought forward by Badal, in 1882, for ciliary neuralgia, and he also suggested that it might be effective in certain forms of glaucoma, and even in sympathetic ophthalmia. Abadie followed by stretching the nerve in a case of glaucoma, where the eye continued hard and painful after sclerotomy and iridectomy. He stretched the nerve till it ruptured, and then removed a piece of it one cm. long. Tension sank in three days to normal, vision slowly and slightly improved, and the pain was relieved. He has since then reported cases where stretching was advantageously combined with iridectomy or sclerotomy, even in such an unpromising disease as congenital hydrophthalmos. But he expressly states that he does not think nerve-stretching can yet supplant iridectomy or sclerotomy; it should be reserved for intractable cases which have resisted all other measures. He suggests its probable utility in congenital hydrophthalmos, and also in glaucoma in children secondary to anterior synechia, on the ground that the loss of the eye is due to continuous traction on the nerves entangled in the scar. In glaucoma, he combines it with simultaneous sclerotomy.

Brailey has tested the efficiency of the operation to relieve ciliary neuralgia and to lower tension in six cases. In one case he stretched the supra-orbital nerve also to compare the effect.

(1) A man, aged forty-nine, glaucoma; the result of iritis following a cataract extraction five years ago. Tension slightly in excess a month after extraction, but for five weeks had been much heightened, and vision failed rapidly. Supra-trochlear nerve stretched to rupture, and four mm. excised. In three days tension had fallen from +2 to $+\frac{1}{2}$, and in six days was normal. Vision slightly improved. Pain wholly relieved

(2) A man, aged sixty-seven, *glaucoma absolutum* of right eye. Tension +3; perception of light. Sight lost gradually twenty years before; considerable pain. Supra-trochlea nerve stretched. Considerable suppuration of wound. Tension gradually fell, and ten days

[1] Berliner klin. Wochenschrift, 1884, No. 27.

[2] Berliner klin. Wochenschrift, 1885, No. 16.

[3] British Medical Journal, October 10, 1885.

later, was not more than +1. Pain entirely relieved, and had not recurred after some months.

(3) Woman, aged forty-one. Double iridectomy for glaucoma three years ago. Still some tension in each eye, with continuous pain over left brow. Eserine gave no relief. Both supra-trochlear nerves stretched. Wounds healed rapidly. Tension fell to full in right eye, and normal in left. Pain entirely ceased for a month; then both pain and tension recurred, but neither symptom quite so acute as before. Vision remained the same, 6-60 right; 6-24 left.

(4) Woman, aged sixty-three. Left, absolute glaucoma, tension +3, vision nil, some pain; right, tension +3, vision 6-12, inflammatory symptoms slight. Stretching of both supra-trochlear and supra-orbital nerves. No relief of pain, though tension fell to +1. Subsequent sclerotomy, and then iridectomy right, with result that vision remained 6-12, although tension continued +1. The other eye remained as hard as ever, and was finally removed.

(5) Man, aged seventy-five, absolute glaucoma of left eye, with severe pain. Stretching of supra-trochlear relieved pain much, but in five days it returned almost as bad as before. Eye enucleated.

(6) Woman, aged fifty-five, severe choroido-cyclitis of both eyes. As a last resort, the nerve was stretched on each side. Pain was diminished for a time, but inflammatory attacks soon recurred.

Brailey states that he intends, in future, to restrict the operation to diseases in which, on the strength of these cases, there is good ground to expect benefit; in the neuralgia of glaucoma absolutum, and in intractable cases of glaucoma generally. He is satisfied that stretching the *supra orbital* nerves has no beneficial effect on the tension, and only doubtful, at best, on the neuralgia. Stretching of the supra-trochlear, he believes, does have some influence on the tension, but it is not worth counting on, in this respect, as a remedy for glaucoma, though it is of use as an adjunct.

GLIOMA OF RETINA.—THREE CASES IN A FAMILY OF FIVE CHILDREN.

Macgregor[4] briefly records the following interesting family history: Father living, and in good health; mother died at the age of thirty-four, of "disease of the liver and heart." The left eye of the eldest child was removed when he was two years old; the tumor recurred in the stump, and also affected the right eye. The left eye of the second child was removed when the child was three months old; nine months afterward the right eye became affected, with fatal result in a few months. The third child was six years old, and in good health. The fourth child had the left eye removed when he was seventeen months old; nearly two years afterward the right eye became affected, sight was lost, the eyeballs protruded, and when, at four years of age, he was admitted to the hospital, the orbit was completely filled with a red, fleshy, pulsating tumor, which protruded more than an inch beyond its margin; death a few days later, apparently from exhaustion. The fifth child was fifteen months old, and, so far, had shown no symptoms of the disease.

PERIPHERAL ATROPHY OF THE OPTIC NERVE.

Fuchs,[5] by the examination of a large number of optic nerves, thinks he has established the anatomical fact that in the human adult, there is, as a rule, an atrophy of certain nerve-fibres. The fibres which are thus subject to a physiological atrophy, are situated: *First*, immediately beneath the pial sheath of the nerve. *Second*, about the central vessels, which are accompanied, as is well known, by a continuation of the pial sheath.

The peripheral atrophied fibres lie between the sheath of the nerve and a septum not heretofore described, which is concentric with the pial sheath. This septum, to which Fuchs gives the name *peripheral septum*, lies at a distance of 0.03 mm. to 0.06 mm. from the pial sheath. It may be either continuous and regular, or it may be divided irregularly by prolongations of the pial sheath; it is limited to the anterior portion of the nerve. In one case, Fuchs found it as far forward as the lamina cribrosa, and in the majority of cases it was found at a distance of one mm. behind the bulb; from thence, it extended backwards for fourteen to fifteen mm. This anatomical peculiarity is not represented on any of the drawings of sections of the opticus that have ever been published, with the single exception of a diagram published by Edmunds and Lawford.[6]

Fuchs does not consider it possible that this septum can be, in any way, a consequence of the degenerative process, but on the contrary, regards its existence as an essential factor in the production of the atrophy, as will be seen in what follows.

Between this peripheric septum and the pial sheath, lie the *peripheric atrophic bundles* of nerve-fibres. Here, in the adult, the substance of the nerve-fibres has disappeared, and only an empty network remains, namely, gray atrophy. This condition, anteriorly, completely envelopes the nerve, but becomes perforated more and more by healthy bundles of nerve-fibres posteriorly, until it can no longer be traced, and disappears, together with the now incomplete peripheral septum.

A central atrophy is always to be found about the central vessels. Here, the degeneration does not consist of bundles of nerve-fibres standing alone, as in the peripheral form, but of small, somewhat separated portions of bundles. It can be followed back accurately to the point of exit of the vessels from the nerve. From that point backward there is none. This central atrophy is always less marked than the peripheric, but is, nevertheless, to be found in every adult nerve.

The degeneration, central and peripheral, apparently proceeds with varying speed in different individuals. Before the thirtieth year it appears very slowly, and at the most, the bundles in which the substance of the nerve-fibres has disappeared are not numerous. Even after the thirtieth year occasionally nerves are seen in which a redness of the nerve-fibres of the peripheral bundles is the only change to be found. As a rule, however, after the thirtieth year it is well marked, although its rate of progress and ultimate extent varies in different individuals. The atrophy of the nerve-fibres which surround the central connective tissue is of the same character as that in the peripheral bundles. The degeneration which is found is a species of gray atrophy, such as Leber has described. Fat cells, such as are observed in atrophy of the nerve in cases of tabes, are never seen in this form of degeneration.

Fuchs examined more than sixty cases, of all ages,

[4] Medical Times and Gazette, July 11, 1885.
[5] Archiv für Ophthalmologie, Bd. xxi, Hft. I.
[6] Transactions of the Ophthalmological Society of the United Kingdom, 1882, 1883, plate xiii.

and concludes that the atrophy is not the result of inflammation. The fibres so affected lie in contact with the pial membrane of the sheath of the nerve in the peripheral form, and with the prolongation of that membrane about the vessels in the central form. In the periphery, the above-described peripheral septum shuts them off from the remaining portion of the nerve.

Our author concludes that the result may be due to the repeated congestion of the pial membrane, which, being filled with blood, compresses the fibres lying contiguous to it, and so causes the atrophy. In the peripheral form the bundles of fibres which lie external to the peripheral septum are at a double disadvantage, as they are compressed between the two membranes. Moreover, the lymph spaces are especially numerous beneath the pial sheath and around the bloodvessels, and they may play an important rôle in this degeneration, injuring the nerve-fibres either mechanically, through compression, or chemically, through imbibition.

The functional consequence of this atrophy would, theoretically, be an enlargement of the blind spot, since it has been shown that probably the fibres that form the most external layers of the optic nerve at its anterior extremity, supply the retina immediately about the optic disc.

RELATIONS OF THE EXTERNAL OCULAR MUSCLES TO THE VENÆ VORTICOSÆ.

Fuchs[7] has made a study of the topographical anatomy of the eye to determine whether, and if so, in what manner, a compression of the venæ vorticosæ by the external muscles can take place. He was prompted to this investigation by a statement made by Von Arlt, that such an action of the muscles during convergence produced acquired myopia through the congestion of the uveal tract. He accurately measured the distances of the points of insertion of the various muscles from the margin of the cornea. This he did in fifty-five eyes, thirty-one emmetropic, twenty myopic, and four hypermetropic.

In the case of the recti muscles, he found that while they were inserted with considerable symmetry with regard to the horizontal and perpendicular meridians of the eye, yet their distances of insertion from the margin of the cornea might vary considerably, even in the same eye. He also found that the breadth of the tendinous insertion did not correspond with the strength of the muscle. The rectus superior, the weakest of the four recti, always had the broadest insertion.

In myopic eyes, the insertions were broader than in emmetropic eyes, but were not farther removed from the margin of the cornea, which would indicate that the anterior half of a near-sighted eye is enlarged in its equatorial diameter, but not in its antero-posterior diameter.

He found that the line of insertion of the obliquus inferior made an angle of 19° with the horizontal meridian, but that of the obliquus superior of 45° with the same meridian, so that it is not correct to describe their lines of insertion as parallel, as is done in most of the text-books. The breadth of the insertions of the oblique muscles was found to be considerably greater in myopic eyes than in emmetropic eyes, which is without doubt, due to the stretching of the sclera, as these muscles are inserted far enough posteriorly to be attached to that portion of the sclera which suffers most in myopia.

The venæ vorticosæ are divided into two pairs, an upper and a lower pair. The vertical meridian divides each pair. Both pairs pierce the sclerotic posteriorly to the equator of the eye, the upper pair at a distance of seven to eight mm., and the lower pair at from five and a half to six mm. In hypermetropia they were found nearer the margin of the cornea than in emmetropia, on account of the short axis of the hypermetropic eye; in myopia, on the contrary, the distance is the same as in emmetropia, showing that the distension of the sclera in the myopic eye makes the distance between the veins of each pair greater than it is in an emmetropic eye.

The study of the relations of the venæ vorticosæ, is, of course, the objective point of the paper. With regard to the four recti, the externus and the internus never over-lap the veins, and although the superior and inferior are so placed that their edges, and sometimes their surfaces, are in close relationship to the points of exit of the veins nevertheless, this occurs so far behind the equator, that they cannot exercise any pressure on the veins. With the oblique muscles, however, the conditions are very different. The obliquus superior may be so situated as to press on the point of exit of the upper and outer vein. In hypermetropia and emmetropia, the condition was found in twenty-three per cent. of the cases, while in the remaining seventy-seven per cent., the exit of the vein was so far behind the equator as to render this impossible; in myopia, this condition is reversed, and in seventy-three per cent. of the cases pressure could be so exerted. The upper and inner could be so compressed in only a very small proportion of the cases, and these were not myopic eyes. The obliquus inferior was found to be so placed that it invariably exerted pressure on the external lower vein, but never on the internal.

In the use of the eyes for distant vision this pressure of the obliques would be constantly interrupted, and the alternate contractions and relaxations of the muscles would assist the venous flow. In continuous use of the eyes for near work, the obliques would, in a large proportion of myopic eyes, exert a constant pressure on one vein of each pair, which would certainly lead to obstruction of the circulation, and perhaps to an increase of the myopia. On the other hand, Fuchs sought in many sections of emmetropic and myopic eyes for dilatation of the venæ vorticosæ, without finding such a condition present in a single case.

Hospital Practice and Clinical Memoranda.

A CASE OF MULTIPLE SARCOMA OF THE SKIN.[1]

BY C. A. CHEEVER, M.D., OF MATTAPAN.

On the 3d of June, 1884, I was consulted by an American lady about sixty-five years of age, for ulcers on her legs. Her history was that she had always been well until a short time before seeing me. She had never been subject to any skin eruption, sore throat, headache, or in fact, any of the indications of constitu-

[1] Read before the Norfolk District Medical Society, Dec. 29, 1885.

tional infection. She had had two children only, both of whom had attained adult age. She thought she had had the ulcers about six weeks.

Examination disclosed three ulcers, situated one on each leg about four inches below the patella, and just at one side of the crest of the tibia, and one on the right thigh, at the junction of the lower and middle thirds, and upon the postero-external aspect. The ulcers all had healthy granulations in the centre, while the edges had a grayish and glazed appearance, were indurated, and somewhat elevated.

Those on the legs were each about the size of a silver dollar, and nearly round. The one on the thigh was about twice as large and oblong; the upper part was excavated to a depth of about a third of an inch, the lower part less deep, and surrounded by indurated tissue for about an inch on each side, freely movable on the deeper tissues, and apparently about an inch in thickness.

Finding quite a number of marked varicose veins, and nothing else appearing to cause the ulcers, I attributed them to the veins, and applied suitable treatment for that condition.

July 1st. The ulcers were looking better, and one of them was decidedly healing.

July 15th, I found a new condition of affairs; an efflorescence on the legs and arms of pinkish nodules, the size of a pea, freely movable on the deeper tissue, hard and elastic, with sharply-defined margins. On the forearms, were several nodules larger than the others, which the lady said had been there for some time; these were exfoliating fine, silvery white scales, and one of them as large as a nickel, had on the centre a brownish, semi-transparent crust. I was then told that the ulcers on the legs had been preceded by similar growths.

Although I could find no history of syphilis in the family, I thought the efflorescence, taken as a whole, more nearly resembled some of the later manifestations of that disease than of any other. I then gave, in addition to iodoform externally, red iodide of mercury, gr. 1-30, and iodide of potassium, gr. 2½ t.i.d.

August 1st, I found that the small papules had increased both in size and numbers. I was also shown on the crural region of both thighs, several ulcers of the size of a silver quarter-dollar. I counted between twenty-five and thirty diseased places in all stages of development, from the pink papule to the ulcer as large as the palm of the hand.

The process of ulceration was seen to begin on the surface, and at the centre of the nodules, when they were about an inch in diameter; and under cover of a crust yellowish or greenish-brown in color, it extended toward the edges, but at the same time, the nodules continued to grow laterally, so that by the time the new growth was removed by ulceration, the remaining ulcer would vary from one and a half to three inches across. The efflorescences were scattered without order or symmetry, over both lower and upper extremities. The head was free from them, and I was told that the body was also free. There had been no itching or burning at any time; the nodules were entirely painless and not sensitive; the ulcers have given but very little pain, and that has been confined to a few of them.

Aside from the skin trouble, and a certain nervous or mental depression, she seems perfectly well; her appetite is excellent, she sleeps well, bowels regular, her color has improved, and the varicose veins have disappeared. She had, however, a marked disinclination to talk about her trouble, or to have any one know the extent of the disease; and from what I learned later, I am very certain that at no time, did I see all of the disease. The mercury salt was increased to 1-20 gr., and the iodide of potassium to 5 gr. t.i.d.

September 1st, the ulcers were all healing, except the smallest ones with the elevated ring-shaped margins of new growth, and some of these craterform rings were undergoing absorption, as were also some of the smaller nodules that had not reached the stage of ulceration. No new papules had appeared. She felt well, and thought she was getting well. The iodide of potash was increased to ten grains t.i.d.

September 25th, she still appeared to be doing well. Some of the ulcers had entirely healed, forming a somewhat soft and deeply-pigmented cicatrix covered with a moist, scaly, and yellowish crust, exfoliating in pieces as large as a little finger-nail. The nodules appeared to be undergoing absorption; no new papules had appeared, but she complained more of nervousness than before. At this time, I tried to have a consultation, but the patient was unwilling, and it was postponed; but in conversation with Dr. J. C. White, I told him of the case much as described above. He agreed with me in thinking the disease seemed more like syphilis than any other, and at his suggestion, the iodide of potash was increased to fifteen grains t.i.d.

Several of the ulcers were healing rapidly, no new efflorescences had appeared. Her appetite was ravenous. She complained now, occasionally, of swelling of the feet and ankles. The urine was examined at intervals, and found normal each time.

November 9th. One new papule had appeared on the right leg near the knee. Several tumors had disappeared from this region, while others had ulcerated and were healing.

She was not sleeping well, and as her husband believed the medicine was the cause of her sleeplessness, I diminished it one-half and added one-half drachm of fluid extract stillingia comp. to each dose.

There formed about this time on the flexor surfaces of the fore-arms about a dozen new papules, resembling in every way those first described. At this time I was shown a tumor on the outside of the left thigh of a leaden gray color and about the size of a silver dollar, surrounded by an area of red and highly inflamed skin. The gray central and evidently necrosed tissue I removed with the knife, giving no pain and causing but very little hæmorrhage. The cut tissue was pearly white, soft, quite friable, and about three-fourths of an inch thick. Underlying it I found a layer of healthy granulations from which the necrosed tissue was separated by a layer of pus. With a poultice for a few days, iodoform powder, etc., the remaining ulcer was entirely healed in a week.

December 1st. She was failing all the time in appetite, strength and sleep; on the other hand, many of the ulcers had entirely healed, and the others were healing. Quite a number of the nodules had become entirely absorbed, the others were diminishing in size. Some had been absorbed more rapidly from one side than from the other, leaving crescentic ridges; growing from one of these ridges on the right forearm was a nodule much thicker than any of the others, with a thin, red, exfoliating epidermis and several small

veins coursing over it; this was the only tumor that showed a special fungating tendency, and was the one that was later on submitted to the microscope.

Some of the tumors had enlarged and become fused to neighboring ones, although for the most part they were discrete.

Two more large tumors on the leg had necrosed, and been removed. She was now reported as being delirious at night, and as sleeping only about two hours. The bromides have no effect.

December 16th. To-day Dr. J. C. White saw the patient with me. He said that from the appearances and history alone one could not tell positively if the disease be syphilis or sarcoma cutis, that some of the lesions if not accompanied by the others would be considered characteristic of syphilis, while considered as a whole the disease much resembled sarcoma, and that the microscope would furnish the only means of making a positive diagnosis. Still, from the fact that she had been so long on the mixed iodides without special improvement, he thought best to consider and treat it provisionally as a case of sarcoma, and although he could give very little encouragement for recovery he advised using Fowler's solution. A few day later I removed the top of the fungus-like growth on the right forearm; the cutting gave no pain, and very little bleeding was caused. The specimen was placed in alcohol and given to Dr. W. W. Gannett, whose report follows.

During the following week she rapidly failed, so that by December 21st, I found her in bed and attended by a nurse.

She was delirious, had a very rapid pulse, increased frequency of respiration, lips dry and cracked, tongue brown and coated; the ulcers had rapidly extended and many new papules had appeared. Brandy was given freely and morphine at night. All other medicine was omitted.

From this time to her death, which took place January 6th, 1885, there was a gradual failure; much of the time she failed to recognize those about her. The ulcers and tumors rapidly increased, both in size and numbers, so that at the time of death there were about two hundred of them, in all the different stages of development that have been described. All parts of the body, except the head, were invaded.

No autopsy was made. I learned from the family that the disease had been of about eleven months duration.

Dr. Gannett reported as follows: —

REPORT OF TUMOR REMOVED FROM THE SKIN BY DR. C. A. CHEEVER, AND SENT BY DR. J. C. WHITE, DECEMBER 20, 1884.

An ovoid nodule, measuring ten millimeters transversely, four millimeters vertically, of a rather firm consistency, grayish color. After hardening in Müller's fluid and alcohol a series of vertical sections was made with the microtome. The outer surface of the nodule was covered with a thin layer of epidermis. In the middle portion no evidence of a papillary layer remained; in the lateral portions a few papillæ were to be seen. Beneath the thin epidermal layer, extending to the base of the nodule, and occupying the seat of the corium and subcutaneous connective-tissue was a tissue made up wholly of small spindle-cells arranged in bundles; the bundles having various directions with reference to each other.

The nuclei of the cells were round or oval, and sharply defined. In some places a few delicate connective-tissue fibres could be made out lying between the cells, but there was nowhere any suggestion of an intercellular meshwork. But few bloodvessels were to be seen.

The tumor belongs to the connective-tissue series. From its abundantly cellular character and atypical appearance it deserves the name of sarcoma. From the form of the cells it is to be designated as a small spindle-cell sarcoma.

Diagnosis. Small spindle-cell sarcoma of the cutis.

W. W. GANNETT, M.D.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY.
SUFFOLK DISTRICT.
SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

DECEMBER 9th, 1885. The meeting was called to order at eight o'clock, by DR. F. I. KNIGHT, chairman. The records of the last meeting were read and approved. A letter was read by the Secretary, relative to employing a stenographer for the purpose of taking short-hand notes of the proceedings of the section, but it was thought inexpedient to take any steps in this direction at this time. The regular business of the section was then taken up.

The first paper was by DR. G. M. GARLAND, of Boston, entitled

"SOME CASES OF REFLEX NEUROSIS."[1]

The cases were all at the Carney Hospital, and were the subject of close observation by the house officer, Mr. Gleason. They present a series of strange phenomena in the domain of reflex action, and are, for this reason, of interest. The discussion was opened at the close of the paper by Dr. Rotch, who spoke as follows:

"Mr. Chairman, the cases described by the reader are of unusual clinical importance from the fact that they occurred in adults, in whom symptoms of reflex origin are rare in comparison with infants and children, where this class of cases reaches its highest development, owing to the hypersensitive condition of the child's nervous system. These reflex phenomena are so pronounced in early life that we recognize in them the most serious obstacle to our making an accurate diagnosis, knowing well that any one of them may at times represent many and entirely opposite forms of disease, although the lack of speech of the infant, and the incorrect answer of the older child appear, at first, to offer the greatest barrier to a proper appreciation of the case.

As general examples of reflex symptoms, we have the different forms of eclampsia, the vomiting of cerebral disease, and the earache arising from irritation in the mouth during the dental periods. I will mention some special cases occurring in my practice which seem to illustrate the class of cases referred to in Dr. Garland's paper.

CASE I. A child two years old was seized with dyspnœa and cough, which continued until a purulent discharge from the ear drew attention to that organ,

[1] See page 25.

and inflation of the eustachian tube was followed by immediate relief to the symptoms. There had been no other signs of aural disease, and a physical examination had disclosed nothing abnormal in the heart or lungs.

CASE II. A child four years old had a chronic otorrhœa; whenever treatment directed to the ear stopped the discharge, the child began to have what appeared to be a laryngeal cough, though nothing abnormal could be found anywhere on examination of the air passages; the cough would continue until the discharge from the ear returned, and then would cease, and this reversal of symptoms would occur four or five times in a year.

Two cases seen in consultation with Dr. Minot presented the following peculiarities, illustrating the difficulty of making a diagnosis from the rational signs, on account of misleading reflex symptoms. Case I had pneumonia of the left dorsal base. Case II had acute inflammation of the middle ear. When seen by Dr. Minot, the child with pneumonia had normal respirations, no dyspnœa, pale skin, and was sleeping quietly, while the child with ear trouble had respirations of sixty to seventy, dyspnœa, flushed face, and was relieved by inflation of the eustachian tubes.

Rosenstein's case of supposed purely reflex neurosis of the intestine is worth mentioning. A boy nine years old began to vomit fæcal matter, and, at the same time, to have fæcal discharges from the rectum. This continued for five weeks, with short intervals, and finally disappeared and did not return. Enemata in this case caused both rectal discharges and stercoraceous vomiting, and the treatment which finally gave relief was the administration of Bromide of Potash and Chloral.

Another class of cases supposed to arise from gastric irritation is the so-called asthma dyspepticum — where infants and children are seized with rapid respiration, dyspnœa and cyanosis, the temperature remaining normal, and nothing but harsh respiration being found on examination of the thoracic organs. These symptoms are promptly relieved by an emetic, and are probably due to irritation of the vagus.

Under the head of a reflex neurosis we may also possibly classify peculiar nervous phenomena which I have met with at my children's clinic at the Boston Dispensary, where the sole symptom in one case, a boy of five years, was hiccough, lasting for many weeks, and in another, a boy of nine years, gasping respiration occurring every three or four minutes. We must, however, allow that these last two cases might have been symptomatic of hysteria, or of simulated disease, for the purest type of the disease hysteria, is represented in young children, especially in the first four or five years of life, where the simulated symptoms of the malingerer, marked examples of which I have met with, would be extremely unlikely to arise as a complication.

Finally, there is a class of cases in which I am especially interested, and which, after carefully investigating, and having ample opportunity for following closely and making a precise eliminative differential diagnosis, from digestive disturbances and organic disease of the stomach, I am forced to consider a reflex neurosis, connected possibly with the great abdominal ganglia of the sympathetic; perhaps some shock to these ganglia causing a temporary paralysis of the controlling sympathetic nerve filaments of the stomach, resulting in uncontrollable gastric peristalsis. The patient, whether infant or child, is in perfect health up to the onset of the attack; it then suddenly begins to vomit, and this, in some cases, is repeated regularly every fifteen minutes by the clock, for many hours; or it will vomit, then seem pretty well for twelve or even twenty-four hours, and then have continuous vomiting for eight or ten hours; then the intervals of vomiting grow longer, and the attack stops suddenly in about thirty-six hours, after which the patient rapidly regains its strength; this may occur many times during the year, then may omit for a whole year, but pretty surely returns, and usually lasts until puberty. Absolutely no other symptoms could be discovered in these cases, excepting great thirst and prostration, following the loss of fluid from the body, and the mechanical fatigue. The temperature was usually found to be normal, and the bowels not especially constipated; the cases were evidently not induced by the ingestion of improper food; in young infants, the prostration was at times so great as to produce serious doubts as to their recovery. All treatment directed to controlling the vomiting has so far, failed, the disease apparently being self-limited, but the main factor in supporting the patient's strength during the attack is to from time to time, according to the pulse and general aspect, produce sleep, which is accomplished by enemata of Bromide of Potash and Chloral, which at times also seem to render the intervals of vomiting longer, though they do not materially shorten the length of the attack. The late Dr. Calvin Ellis saw a number of these cases, and considered them of reflex origin.

Dr. Minot also was of the same opinion when he saw a case of this kind with me. I have never heard of a death from this disease, but I think that in young infants it might occur from exhaustion unless sleep could be produced. I am inclined to attribute the cause clinically to exhaustion of the sympathetic from some shock, perhaps mental, in peculiarly sensitive subjects, and I have arrived at this conclusion by a process of careful elimination, no definite point of irritation so far having been discovered in other parts of the economy, nor any proof that there has been irritation of the gastric terminal filaments of the vagus.

The cases occurred at all ages and among all classes, and I would say once more that the theory which I have advanced as a cause of this disease is the result of six years' clinical study of special cases, and that I present it to this Section for Clinical Medicine with much modesty; for so far as I know, no one else has as yet concurred with me in my idea as to the sympathetic ganglia being the nidus of the disease, although all agree, so far as I know, that it is of reflex origin."

DR. HENRY I. BOWDITCH stated that he was much interested in the subject of the paper, which is a matter of great importance to the physician. The cases mentioned by Dr. Rotch do not fall into the same category as those contained in the paper. Dr. Bowditch never thought of these cases as caused by a reflex neurosis, but as caused by some disturbance of digestion. It is to be regretted that the reader has not given us a *résumé* of the present state of science on this subject.

Dr. Bowditch spoke of a woman whom he had recently seen, in consultation, who had some menstrual trouble, accompanied by constant cough. No positive

causes could be found for the symptoms, but a sensitive spot was discovered in the lower right abdominal region. The diagnosis of threatened abscess of the broad ligament was made, with tumefaction of the ovary. This was the cause of a severe cough which was in this case evidently of reflex origin.

DR. BLODGETT mentioned a case in which a man of middle age was the subject of a periodical attack of what he called "biliousness," which always commenced by a feeling of dull distress in the region of the liver, and was soon followed by a swelling of the lower jaw; but upon the other side, that is to say, on the left. The swelling is very painful, so that the patient is obliged to give up all business and keep the house, and at times to remain in bed. The curious part of the case is that a prompt cathartic will cause the swelling of the jaw to disappear in a few hours, with complete relief to all the symptoms. The jaw gives no further trouble until another attack of "bilousness" occurs, when the former symptoms reappear in all their intensity.

DR. GARLAND. in closing the discussion, stated that our present knowledge of reflex phenomena is not at all satisfactory. In Germany much interest is at present manifested in the subject of reflex neurosis, and cases are reported corresponding closely to those described by Dr. Rotch. Dr. Rotch's cases of vomiting well illustrates in children the same phenomena which Professor Leyden has noticed in adults, and Professor Leyden reports a case of this kind where the post-mortem examination showed no organic disease, and where the symptoms during life consisted merely of continuous vomiting. This subject also occupied largely the attention of the German Congress of 1884, and the discussion was opened at that time by Professor Leube. Dr. Garland also said that a year ago, he had met with a case which illustrated this condition of gastric neurosis, the symptoms being vomiting and the autopsy negative.

DR. H. C. HAVEN read a long and valuable review of our present knowledge of rachitis, following it by a description of the investigations which he has been for some time prosecuting at the West End Nursery, and which seem to show a decided preponderance of cases of this disorder among the children of colored parents. The paper was accompanied by elaborate tables, showing the state of development of the patients, their food, when weaned, etc.

DR. ROTCH, in opening the discussion, stated that he did not remember the exact number of the cases of raehitis which he had seen at his clinics at the City Hospital, Boston Dispensary, and Children's Hospital during the last two years, but that he had collated them, and that he was under the impression that the number of cases where it occurred in colored children was small in comparison to the white. This might, however, be accounted for by the fact that his clinics were not situated in a colored district, while the Dispensary of the Infant Hospital was in a portion of the city thickly populated by the colored race. This might bring a larger number of colored rachitics under Dr. Haven's care, but still would not account for the large per cent. of rachitics among the whole number of colored patients.

Dr. Rotch agreed with Dr. Haven as to the probable influence of climate as a cause, but he also offered the following suggestions as perhaps aiding the future study of the subject.

It has been noticed by some of our Dispensary physicians that venereal disease is especially common among the colored portion of the population. If this be so, and syphilis is more common among the colored people, hereditary syphilis would also be more common, and although we recognize that there is no direct connection between syphilis and rachitis, yet, for some years, the most prominent physicians in children's diseases in Germany have held that even where hereditary syphilis has been cured, these same children are more apt to have rachitis than those who have not had syphilis, simply from their syphilis having left them in a condition favorable to the development of a disease, such as rachitis, represented by impaired nutrition.

Dr. Rotch also said that the number of rachitics which were presented at his clinics had increased during the last six or seven years, and that he remembered being struck by the small number of cases of rachitis which he encountered among large numbers of poor children who came under his observation on his return from Vienna some years ago, where the number at that time was much larger proportionately than in Boston, and yet where the physicians insisted on calling the disease the "Englische Krankheit."

Dr. Rotch also drew attention to the results of autopsies observed by himself and others, pointing towards a possible rachitic condition of the bones of white children, without any manifestation of this condition during life, the cases merely being diagnosticated and treated as debility from impaired nutrition. Thus a well-marked rosary is at times found on the inner surface of the costal cartilages, where no suspicion of such a condition was detected during life, and it may be that there is a greater predisposition among the colored race to show the external manifestations of rachitis than among the whites.

DR. BOWDITCH remarked that Dr. Haven had made an important addition to our knowledge upon the racial and climatic relations of rachitis, and expressed the hope that he would carry on his observations to a still further extent, and by means of the United States Consuls or other officers of the government, obtain information as to the condition of the colored populations in Africa.

DR. HAVEN replied that he had endeavored to obtain the desired information from the National Library at Washington, but has not been successful.

DR. F. B. HARRINGTON, of Boston, then read a paper on

THE PULMONARY COMPLICATIONS OF TYPHOID FEVER[2],

in which was presented a series of cases, in the course of which more or less serious impairment of the pulmonary organs was noticed.

DR. VICKERY remarked that in the stupor which is often associated with typhoid fever, it is easily possible that portions of food may be aspirated into the lungs, thereby inducing a pneumonia from the presence of the foreign body in the air passages.

DR. BOWDITCH stated that in typhoid fever there is often a lack of the more striking symptoms belonging to other serious diseases, so that they may often be easily overlooked. All febrile diseases present the same general features as certain cases of typhoid, and many cases are, no doubt, ranked as typhoid which are in reality something else. It is certain that many pulmonary affections are ranked as typhoid which have nothing to do with that disease.

[2] See page 28.

DR. HAVEN showed an improved form of stethoscope, consisting of an ordinary Cammann instrument in which the usual flexible tubes are replaced by similar tubes about two feet in length, which allows the physician to stand at a somewhat greater distance from the patient, and, in some cases, as, for instance, in the presence of pediculi, is a source of great comfort. In the examinations of children it is of much convenience, as it allows greater adaptation to the movements of a fretful patient. It is quite portable, and gives almost the same concentration of sound as does the ordinary instrument.

Dr. Haven also showed an improved form of nursing bottle, by which the natural conditions are more perfectly imitated than in the forms of bottle generally in use. It consists of a flattened and elongated glass bottle, one side of which is removed so that the atmosphere may exert its normal pressure on the contained fluid, and thus imitate the normal conditions of infant feeding. Another desirable feature is that every part of the bottle is accessible to cleaning, and a rubber nipple is used in which several fine holes are made by a cambric needle. The effort of suction by the child is sufficient to excite the salivary glands of the child's mouth, and thus promote the normal digestion of the food.

DR. BOWDITCH called the attention of the section to the fact that the Society possesses no treasury, and has no funds at its disposal for any purpose. He moved the appointment of a committee by the chair, whose duty it should be to suggest some plan at the next meeting whereby the small sums necessary for the purposes of the Section might be provided. The motion was seconded by Dr. Haven, and was passed by the Section.

THE CHAIRMAN stated that he would appoint the committee at another time, and would inform them of their duty.

Adjourned at 10.15 o'clock.

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting, December 17, 1885.

DR. T. GAILLARD THOMAS read a paper on

VAGINAL AND VULVAR ENTEROCELE.

There were, he said, five varieties of hernia which may show themselves by the vagina and vulva, namely: (1) cystocele; (2) rectocele; (3) vaginal enterocele; (4) pudendal enterocele; (5) perineal enterocele. Other varieties, if the subject were treated in minute detail, might also be given, based on the contents of these hernial sacs, in which the ovaries, the uterus and the fallopian tubes, either empty or filled with the products of conception, have in exceptional cases been found; or upon some extremely rare and extraordinary development of this condition, such as in one case of Burns, referred to by Sir Astley Cooper, in which the base of the bladder, passing down alongside of the right wall of the vagina, formed a hernia in the labium majus of that side. But, for practical purposes it was only necessary to consider the varieties of hernias named, and the object of the present paper was to study the descent of the intestines through the pelvic roof and their protusions with the labia majora, the vagina, or through the perineum.

He referred to a number of standard works and text-books, and said that it was curious to see how very generally these varieties of hernia had been ignored in systematic treatises on gynæcology; and this was the more remarkable, since errors in their diagnosis were very liable to occur. Even in literature outside of systematic treatises it was difficult to find much upon the subject. Berard's *Dictionaire de Médicine*, published in 1846, gave the best account of it which had come under his notice. Having mentioned various instances of this accident which had been put on record by different writers, Dr. Thomas went on to speak particularly of

VAGINAL ENTEROCELE.

This variety consisted in a descent of the intestines into the pelvic cavity, either in front of or posterior to the broad ligament of one side. As Boyer and Richter long since pointed out, the intestines never descended directly in the median line, either anteriorly or posteriorly, on account of the intimate relations of the vagina at these points; but always descended a little obliquely, and most generally posteriorly. Usually, it was the intestines alone that descended in these hernial protrusions; but sometimes the omentum accompanies them; and usually also, it was the small intestines that composed the hernia, but the large intestines might be involved in it.

Vaginal hernia, as a rule, developed itself in the following way: A loop of intestines gradually pushed downward the prolongation of peritoneum which forms the pouch of Douglas, until it impinged upon the outside of the wall of the vagina, and caused it to arch inwards. This mechanical influence being continued and gradually increased, a tumor formed in the vaginal canal, inverted one wall of that canal more and more completely, and might end by escaping from the vulva and hanging outside the body, as a complete prolapse of the bladder or rectum would do. Under these circumstances, it was evident that the tumor which protruded had for its compound parts, first, the inverted vaginal wall, second, the peritoneum, and, third, the intestines. As Berard had pointed out, it was very important to determine whether the entire thickness of the vaginal wall was inverted and formed the envelope of the tumor, or whether the external coat was torn so as to present an opening through which the hernia passed; and although in the literature of the subject were to be found reports of several autopsies the point apparently still remained unsettled.

Unquestionably the greatest danger attending this form of hernia, as well as the two other varieties that claimed attention this evening, arose from the possibility of an error of diagnosis on the part of the impulsive or unwary surgeon. If the tumor occurred during labor, and obstructed the progress of the fœtal head, it might perhaps be mistaken for an ovarian or parovarian cyst, with a long pedicle, which had been pushed into the pelvis; in which case a trocar and canula might be plunged in, and the operator be horrified at the escape of fœcal matter and intestinal gases. Or, if the condition was found to exist in the non-parturient woman, an effort might be made to remove it, when the operator would be enlightened in a very painful manner in regard to the true nature of the case. In this connection Dr. Thomas quoted two instructive cases that had been reported.

Parturition was the most frequent cause of the varieties of hernia under consideration; but it was to be

borne in mind that some of the most striking cases of the accident recorded had occurred in nulliparous women. These were usually due to violent efforts, falls, and the previous existence of pelvic tumors which had burst or been removed. Vaginal hernia, as long as it remained in the pelvic cavity, and did not interfere with parturition, was usually a matter of little moment, and the source of little inconvenience. Under certain malign influences, however, occurring during parturition, as well as in the non-parturient state, such as pressure from the fœtal head, inflammatory processes, fœcal impaction, torsion of the contents of the sac, or the existence of a neoplasm, strangulation might occur. The symptoms which were then apt to develop were: difficulty in locomotion, pelvic tenesmus, or "bearing-down," dragging sensations, tendency to constipation, and, in time, vomiting. Should the accident complicate parturition, obstructed labor was apt to result. Upon vaginal examination, a tumor of greater or less size was found in the vagina, and was diagnosticated by the following physical signs: It was supple, soft and yielding; decreased upon pressure; gave a sense of gurgling to the finger, if not to the ear; increased upon the patient's coughing or straining; yielded resonance upon percussion; and was very generally reducible if the patient were placed in the knee-chest position and efficient taxis was practised.

Vaginal enterocele might be confounded by a careless and rapid diagnostician with the following conditions; prolapse of the vagina, uterus, bladder or rectum, or with a combination of these displacements; with vaginal cysts; with ovarian or parovarian cysts; with a fibrous tumor presenting low down in the pelvis; or with a marked case of tubal dropsy. Error was likely to creep in from the practitioners being too confident, too much off his guard, and too little inclined to consider the possibility of a mistake. If he approached these cases calmly, philosophically, and in a proper spirit of diagnostic investigation, it was very improbable that an erroneous diagnosis would occur. Having mentioned that most cases presented striking features, he quoted the graphic description of a case given by Sir Astley Cooper in his celebrated work on hernia.

It was to be borne in mind that, like hernia occurring elsewhere, those forms now under consideration might show themselves in two ways: *first*, by a brusque and sudden development, marked by alarming and decided symptoms, and, *secondly*, by a development so gradual and uneventful as to symptoms as to escape recognition entirely until the mere mechanical results of the hernial tumor forced themselves upon the attention of patient or physician. In certain rare instances acute vaginal hernia occurred as a consequence of some traumatic influence destroying the continuity of this canal in its upper part, and Dr. Thomas had himself been personally familiar with two such cases.

PUDENDAL ENTEROCELE.

Pudendal hernia demonstrated its existence by the presence of an elastic tumor about as large as a hen's egg, or a pigeon's egg, about the middle of the labium majus of one side. Having explained its mode of origin, he said that some of the French writers divided this form of hernia into two varieties: (1) anterior labial hernia, and (2) posterior labial hernia. From inguinal hernia ending by descent into one of the labia majora the internal variety might be thus distinguished: (1) The finger, pushing the tumor upwards, will pass into the pelvic cavity between the ischium and vagina. (2) At the level of the os uteri, or thereabout, it will enter the pelvic roof. (3) Pressure being maintained on the inguinal canal, and the patient being ordered to cough, it will, in spite of the pressure, recur.

The following conditions were mentioned as liable to be confounded with pudendal hernia; cyst or abscess of the vulvo-vaginal gland; abscess of labium majus; fatty or fibrous tumors of the labium; tumors descending from the pelvic cavity. Cases in illustration of some of these points was quoted, and Dr. Thomas then said that the differentiation of pudendal hernia from these conditions of the labia should be very carefully considered; for if an erroneous diagnosis were made here, a fatal issue might very probably prove the result. The diagnostic signs which proved most reliable and which might almost be styled pathognomonic were these: (1) Airy feeling upon palpation; (2) gurgling upon replacement; (3) diminished tension in the dorsal decubitus; (4) diminution of bulk upon taxis; (5) resonance upon percussion; (6) percussion upon coughing; (7) intestinal pains of colicky character.

PERINEAL HERNIA.

This might affect both male and female, and in the latter it consisted of the descent of the intestines between the vagina and rectum, the advance being made posterior to the broad ligament, and continuing until the perineal muscles were forced apart, and the gut, with its peritoneal envelope, was arrested by the skin. All these varieties of hernia were usually readily amenable to taxis, and this Dr. Thomas had invariably found to be greatly facilitated by the knee-chest position. In some rare cases strangulation occurred; and under these circumstances the same surgical practice was indicated as in inguinal or crural hernia, namely, cautious opening of the sac, and section of the constricting band by passing up a probe-pointed bistoury.

Before closing the paper he said he wished to put on record a remarkable case of extreme vaginal hernia which presented some features which he had never met with in such literature of the subject as had fallen under his notice. The hernial tumor hung outside the body and reached as far down as the middle of the thigh on the right side; causing the most intense and unintermitting suffering. He performed laparotomy, and as the abdominal walls were cut through (an assistant in the meantime pressing the mass up into the pelvis), he discovered a tumor of apparently a soft fibroid character on a level with the symphysis pubis, which had probably been the original cause of the vaginal hernia. The sac was secured by sutures in the abdominal wound, a glass drainage-tube having been introduced, and the patient made a good recovery. Five weeks had elapsed since the operation, and there had been no return of the pain or other symptoms; but he said that he still felt considerable apprehension in regard to the future.

Dr. H. C. Coe, pathologist to the Woman's Hospital, had examined the tumor microscopically, and expressed the opinion that it was probably an unusual growth of the pelvic connective tissue. Dr. Thomas then referred to several cases of connective tissue growths, such as tumors of the broad ligament, which had been reported by A. Martin, Schroeder and Hoffmeyn, the notes of which had been kindly collected for him by Dr. McCosh.

In conclusion, he remarked that, unfortunately, little could be said concerning the treatment of vaginal or vulvar hernia, for the reason that there was but one variety, the pudendal (which eventuated from inguinal hernia), for which very much could be done. That variety was amenable to treatment by the ordinary truss, as inguinal hernia was. The other varieties could to a limited degree be relieved by pessaries, perineal pads, abdominal bandages, etc.; but we were poor in methods of decided relief, and utterly wanting in those of cure. It appeared to him that the plan suggested and partially carried out in the case which he had related, promised more than any other which had as yet been brought forward; of the validity of this surmise time and experience would have to give the proof. He was certain that if another case of large vaginal hernia should present itself he should feel inclined to try laparotomy; dragging up the sac, and fastening it in the abdominal wound. B. Schmid had stated that attempts were made by Huguier at radical cure of vaginal hernia by an oval excision of part of the posterior vaginal wall, and closure by suture, but without any lasting result. He thought that he must indeed be a sanguine surgeon who hoped for much from such procedures.

Recent Literature.

A Treatise on Nervous Diseases; Their Symptoms and Treatment. A text-book for Students and Practitioners. By SAMUEL G. WEBBER, M.D. pp. 410. New York: Appleton & Co. 1885.

The want has long been felt, especially among teachers and students, for just such a book as this with which Dr. Webber has supplied us: a reliable manual, which should bring together and present in a concise form, and with due discrimination, the facts and opinions which have been multiplying so fast in the special literature of the day.

The task which the author set himself has been, on the whole, admirably performed. The whole range of the more important diseases of the nervous system has been covered, and it is evident, although but few references are given, that the observations of the best authorities, and the results of the author's ripe experience have been carefully utilized.

Above all, it is thoroughly trustworthy. The chapters which strike us as the most susceptible of improvement are the *general introduction*, and the chapter on the *anatomy of the brain*.

In the former, the *methods of testing* the functions of sensations and motion, etc., are excellent so far as they go, but it seems to us that auditory as well as the visual functions should have been considered, and for that matter, the book would have gained in value if a number of other points could have been touched upon which every one must have in mind in making a thorough examination of a patient. Still, we admit that the claims of conciseness are supreme.

The few clinical and therapeutic considerations with which this chapter closes, though themselves highly important, yet leave a sense of incompleteness in the reader's mind.

The chapter on the anatomy of the brain is an excellent summary. Of course so complex a subject could not be thoroughly taught in so short a space, and possibly the real needs of the student and practitioner would have been better met if nothing more had been attempted than a clear statement of the broadest facts in anatomy, in their relation to physiological and clinical facts, such as one would make to a person almost wholly ignorant of the details of the subject. In this way space would have been gained, and, as it seems to us, a more easily remembered even if less accurate impression made upon the reader. Still, here as elsewhere, we are quite ready to admit that it is a question of judgment that is at stake, and that the author's conclusions may have been the best. The diagrams are excellent.

The chapter on *aphasia* might perhaps have been clearer if treated more from a physiological and less from the purely symptomatic standpoint.

All these are, however, minor criticisms on a book which is unquestionably of great merit, and which we hope to see pass through many editions.

The profession in Boston has not been prolific of book-writers, and Dr. Webber's volume is all the more welcome on that account. J. J. P.

Alpine Winter in its Medical Aspects, with Notes on Davos Platz, Wiesen, St. Moritz, and The Maloja. By TASKER WISE, M.D., etc. Second Edition. pp. 121. London: J. & A. Churchill. 1885.

This book is a second edition under a new name of the "Alpine Winter Cure," brought up to date and with an account of The Maloja, its advantages as a health resort, and a description of the new hotel completed this year superadded. This hotel, designed specially for winter residence by M. Jules Rau, a Belgian architect, is fitted with arrangements for the propulsion and extraction of air throughout the building, as well as for the addition of ozone — the inanimate thaumaturgist — to the atmosphere of the corridors and some of the large saloons. The ozone is produced by the surplus electricity at command, the building being lighted by electricity. Elaborate plans are given to explain the system of ventilation and heating, a system which may or may not work as well in practice as it does on paper. One is struck by the fact that the bedrooms contain no open fireplaces, and one thinks of Aiken, S. C., where every room has its fireplace and no extra charge is made for its supply of wood. Directions are given how to reach the Alpine Winter Resort, and the book will be found valuable by those contemplating a sojourn in that region. F. C. S.

— A circular of the National Board of Health, under date December 30, reports three deaths in London during the week ending November 28, ascribed to hydrophobia, making a total of twenty-five from this cause during the current year, against an annual average of six in the past ten years. During the week ending October 3, there were ninety-two cases and forty-four deaths from cholera in the several cities and prefectures of Japan. In Spain, the disease is practically *nil*. In the province of Finisterre, there were sixty-two cases and twenty-five deaths; in Toulon, none. It is also prevalent in the city and province of Palermo, and scattering cases are reported again in the province of Venetia.

Medical and Surgical Journal.

THURSDAY, JANUARY 14, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,

CEREBRAL SURGERY.

THE appearance in book form[1] of Dr. J. B. Robert's views on the "Field and Limitation of the Surgery of the Human Brain," is very acceptable. This writer has done his share in modifying the prevailing opinion on the subject, and his book will serve as a valuable practical aid in deciding the question of operative interference in a class of cases upon which our ideas have been until recently far too conservative. The brain has long been held sacred from the hand of the surgeon, except where the call for operation has been obviously imperative. This conservatism has been due partly to fear of inflammation, and partly to a dread of exposing so delicate and highly organized a structure, presumably the seat of the intellect, as well as the final centre of motion and sensation, to the touch of the examining finger and the knife. It has, however, been long known that large areas of brain matter could be destroyed by foreign bodies, tumors, abscesses and hæmorrhage, with comparatively little apparent damage to intellect or other cerebral function; it has also become an accepted fact that certain localities are devoted to certain functions, and that in many cases the lesion can be traced directly to its lodging-place near or at the surface of the brain and within easy reach by operation. The mortality from trephining *per se*, has been shown by competent authorities to be comparatively low; the dangers arising generally either from the disturbance for which the operation was instituted, from imperfect antisepsis, or from faulty drainage. It has been shown (Yeo) that while death always follows trephining without antiseptic precautions, in monkeys, the mortality may be reduced by such precautions to a very small percentage. Estimates of the mortality in man are of necessity difficult; the lowest is that of Amidon, who places it at a little over three per cent. Nancrede gives a mortality of 10.69 per cent., with a death-rate of 15.29 per cent. to cover the probable risk in trephining a simple depressed fracture. Roberts himself makes the statement that "The removal of portions of the cranium by the trephine or other cutting instrument is, if properly done, attended with but little more risk to life than amputation of a finger through the metacarpal bone." The acceptance of such facts and opinions, even with considerable modification, should lead to a much greater freedom in this direction, for many cases are still doubtless allowed to go from bad to worse under routine treatment, rather than undertake the indicated operation. The case reported by Dr. Witherle, in which a clot was found on trephining, but was allowed to remain rather than enlarge the opening for its removal, illustrates the prevailing conservatism. In marked contrast is the case operated on by Mr. Godlae, where although the opening of the skull revealed nothing abnormal, an incision was made into the apparently healthy brain, disclosing the lesion (a glionæ) whose seat had been previously determined by Dr. Bennett through the aid of cerebral localization. The unfortunate fatal termination of this case, doubly unfortunate on account of its having been regarded by the laity as rather a test of the practical results of study by vivisection, was perhaps due, Amidon has suggested, to imperfect antisepsis and drainage.

Roberts says that the results of the study of cerebral localization are more necessary to the conscientious surgeon than to the neurologist. This statement is hardly to be taken literally, but it is certainly for the advantage of the surgeon to know the symptom atology of lesions about the fissure of Rolando, the most obvious seat for operation, being the region whose functions are most clearly defined. This region, more especially anterior to the fissure, is devoted to motion, the upper third presiding over the opposite leg, or leg and arm, the middle third to the opposite arm, the lower third to the opposite side of the face, and, on the left, to speech. These areas have, probably, no definite boundaries, but may be supposed to shade off into each other as well as into the centres of sensation, which are with less certainty determined, but which are supposed to lie near the corresponding centres for motion, but principally behind the fissure. The directions for finding the fissure are not difficult. The bregma, or junction of the sagittal with the coronal sutures, is the first landmark. This can sometimes be felt, and can always be found by the aid of Broca's Flexible Square, which is simply a draughtman's square made of some flexible metal, with a conical plug at the point of junction. The plug being placed in the ear, and the horizontal arm bent round under the nose, the vertical arm, when bent over the head, will pass over the bregma at the median line. Measuring back from this point five ctm., the upper end of the fissure of Rolando is approximately found. The lower end lies about three ctm. above the end of a horizontal line seven ctm. in length, carried backwards from the superciliary ridge. The line joining these two points, which may be marked out on the shaved scalp, will indicate the course of the fissure with sufficient accuracy for operation, a trephine opening of an inch diameter made over this line, being quite certain to include the fissure. The part of the

[1] P. Blakiston & Co., Philadelphia. 1885.

line selected must, of course, be determined by the extremity or extremities affected. If one opening proves insufficient, others may be made. Roberts quotes the case operated upon by Briggs, in which an area of the skull as large as the hand was removed for epilepsy without evil result, and with relief of the disease.

Roberts's observation is doubtless correct, that there will always remain a greater hesitation in trephining for the relief of insanity and epilepsy, and in the search for tumors, than in cases of hæmorrhage, abscess, and fracture. This will of necessity, be true, partly by reason of the lesser urgency in the former cases, and partly on account of the element of uncertainty in their diagnosis.

CONTAGIOUS OPHTHALMIA IN THE ASYLUMS AND RESIDENTIAL SCHOOLS OF THE CITY OF NEW YORK.

DR. RICHARD H. DERBY, Chairman of the committee appointed last spring to investigate the subject of contagious ophthalmia among the asylums and residential schools of the city, in connection with Dr. John J. Milhan, of the State Board of Charities, Arthur G. Sedgwick, of the State Charities Aid Association, Elbridge T. Gerry, of the Society for the Prevention of Cruelty to Children, and James Gallatin, of the New York Association for Improving the Condition of the Poor, reported that of the fifty of these institutions, the committee had made examinations of many of the most important. These were conducted by sanitary inspectors of the Board of Health, accompanied, in each instance, by experts in ophthalmology, and revealed that a worse state of things exists to-day in most of the asylums visited, than the preliminary report read before the Academy in June last, indicated. Reports received from various reputable physicians, showed that, in nearly all the asylums of the city, children are admitted without due examination of their physical condition, especially as to the condition of their eyes; that no systematic inspection of either the buildings or their inmates, was made by the physicians in charge of these institutions; that no system of quarantine at all adequate was practised; that many of the asylums are grossly overcrowded; and that very grave defects in plumbing have been found. To properly care for the children in them, the committee was satisfied that legislation is needed.

As the conclusion of his report, Dr. Derby presented the draft of an "act for the better preservation of the health of children in institutions," which had been prepared for the committee by Elbridge T. Gerry, Esq., President of the Society for the Prevention of Cruelty to Children. The proposed act provides that every incorporated institution in the State receiving or caring for children (excepting hospitals), shall have attached thereto, a regular physician in good professional standing who shall carefully examine each child applying for admission to the institution, and shall give a certificate in writing, stating whether or not the applicant is suffering from any contagious or infectious disease, especially of the eyes or skin. No child suffering from any contagious or infectious disease shall be allowed to enter or remain in any institution in contact with children not so affected, but shall be immediately isolated, or placed in a proper room or infirmary, which shall be provided for that purpose. It is made the duty of the physician to give notice in writing to the officers of the institutions, whenever any dormitory therein is so overcrowded that there shall be afforded less than six hundred cubic feet of air to each occupant.

The act was unanimously approved by the Fellows of the Academy, who also voted that the committee should be authorized to present it to the Legislature, and use their best endeavors to have it passed. The Committee of the Academy consists of Drs. R. H. Derby, C. R. Agnew, C. S. Bull, David Webster, Gouverneur M. Smith, and the President, Dr. A. Jacobi (ex-officio).

HOSPITAL NURSING CORPS FOR THE ARMY.

IN the recent report of the Surgeon-General of the Army is one recommendation which in our editorial review of the report we omitted to emphasize, but which is a measure of considerable practical importance. This is the establishment of a separate hospital corps of cooks and nurses, together with the increase of the compensation of hospital stewards, in order that men of a higher grade may be induced to accept this responsible position. At present the salary of the hospital steward is from $30 to $34 per month, in addition to which he has a ration and clothing which, being estimated at $14 and $10 per month, make the compensation say $58 per month to a man whose duties are more multifarious and whose responsibilities are nearly as great as those of the post-surgeon, whose pay is seldom less than $200 per month, with perquisites and emoluments of half as much more.

The present system of detailing ignorant enlisted men to serve as hospital cooks and nurses is fruitful of disappointment to the post-surgeons who often see their best endeavors for the treatment of the sick frustrated by the incapacity of ignorant, stupid, or unwilling nurses. Even if a man does get broken in so as to render tolerable service, he is likely at any time to be taken away from the hospital and sent back to his company to please some line officer, or for some small infraction of military discipline, or very often because he is tired of hospital work, just when he has in part mastered it.

The army will doubtless soon secure a separate hospital and ambulance corps, as most of the civilized nations now have. The reforms indicated above are equally called for, and especially in the interest of the common soldier. It is to be hoped that Congress will take the necessary action in accordance with the recommendation of the Surgeon-General.

MEDICAL NOTES.

— We have received the system of books for physicians' accounts, devised by M. L. Hitchcock, of New York, and consisting of ledger and package of twelve monthly pocket day-books. The arrangement of the ledger appears unusually simple and compact.

— An International Committee at Nice, in the interest of the abolition of gambling at Monte Carlo, has prepared a memorial to Prince Charles III. of Monaco, in whose personal interest the gambling establishments are maintained. In this memorial, is included a list of the suicides at Monte Carlo since 1878, all of them being due to disappointment at play, as an immediate cause. The list, which is explicit in names, dates, and other particulars, embraces for the eight years, eighteen hundred and twenty persons.

— An investigation by the medical examiner shows that the Yale student whose recent sudden death was attributed by the physicians to heart disease, and by others to over-exertion in foot-ball practice, was more probably caused by injuries received in an impromptu wrestling match. The examiner found that on the day of his death, the young man had a friendly scrimmage in his room with some friends. In the scuffle he was thrown violently to the floor. This shock, it is thought, caused the blood-clots in his brain which shortly after resulted in death.

BOSTON.

— Surgeon-General Holt intends soon to have a course of instruction upon military surgery given before the Second Brigade Ambulance Corps, which organization proved to be so useful an addition to the brigade at the last encampment. The course will be opened by Surgeon Dixon, of the Fifth Regiment, who will be followed by Surgeon Burrell, of the Cavalry.

— The Massachusetts pharmacy commission held its first meeting on the 5th inst., for the examination of applicants for certificates as practical pharmacists. There were between thirty and forty, of both sexes, who presented themselves for examination. The number of applications for certificates from those entitled to them by reason of three years' actual experience or in consequence of having been engaged in the drug business at the time of the passage of the act establishing the commission, now reaches 2,500.

NEW YORK.

— At the meeting of the Academy of Medicine held January 7th, the annual election of officers took place, and resulted as follows: vice-president, Dr. H. D. Noyes; corresponding secretary, Dr. Wesley M. Carpenter; recording secretary, Dr. A. M. Jacobus; treasurer, Dr. Wm. F. Cushman; Delegates to the State Medical Society, Drs. R. W. Amidon, W. E. Bullard, Gorham Bacon, and A. S. Hunter. A number of amendments to the constitution and by-laws were decided upon, and it was voted that the public should be invited to listen to the annual discourse before the academy.

PHILADELPHIA.

— The Philadelphia County Medical Society held its annual meeting on the 6th inst., for the election of officers and delegates to the State Medical Society and American Medical Association. Dr. R. J. Levis was elected to fill his second term as president, but a very unusual course was taken with regard to the names presented by the nominating committee, for election of delegates to both the State and American Medical Societies. Just before proceeding to the election, new lists were presented and offered as substitutes for the regular nominations, and the new delegates were then elected by an overwhelming majority. The significance of this action may appear upon a careful reading of the following resolutions which were offered by Dr. D. Hays Agnew, and adopted.

"*Resolved*, That at its annual election of delegates to the American Medical Association and to the State Medical Society the Philadelphia County Medical Society desires to express its regret at the action of the American Medical Association at New Orleans, in view of the injurious results which followed to professional harmony and to the prospects of the International Congress.

"*Resolved*, That the delegates from this Society be instructed to endeavor to secure such modification of that action as may best conduce to the re-establishment of professional harmony and to the success of the Congress."

From the above proceeding, which was certainly extraordinary, and the adoption of this resolution, the attitude of the delegation from the Philadelphia County Medical Society, at the meeting in St. Louis may be easily predicted. The meeting at which this action was taken, was by far the largest held by the County Society, and may therefore be considered as representing the feelings of the majority of the members.

— The College of Physicians met on the evening of the same day, the County Society having held its meeting in the afternoon. Col. George E. Waring, jr., of Newport, R. I., read a paper by invitation before the College and invited guests on "The Disposal of Sewage and the Protection of Streams used as Sources of Water-Supply," which was of peculiar interest to Philadelphia at the present time, when our politicians are driving out of office Colonel Ludlow, the city Chief Engineer of the Water Department, because he has rendered himself obnoxious by enforcing the law against manufacturers who were polluting the Schuylkill in defiance of right and authority. On the same evening a business meeting was held at which the following officers were elected. President, Dr. S. Weir Mitchell; vice-president, Dr. John H. Packard; secretary, Dr. Isaac Norris; treasurer, Dr. Charles Stewart Wurts.

The Library Committee reported satisfactory growth of the invaluable collection under their charge: and that they have commenced to issue monthly bulletins of the additions to the Library.

— The annual address was read before the Academy of Surgery, by Dr. R. J. Levis, who took for his theme "Impediments to the Progress of American Surgery," among which he classed "the existence of too many medical schools." At a recent meeting of the Academy, Dr. Thos. G. Morton, reported an interesting case of a boy who had been subjected to the operation for lithotomy at four years of age after which he made a good recovery and was free from symptoms until about one year ago, when thirteen years of age. When admitted to Pennsylvania Hospital he had cystitis and symptoms of vesical calculus but no stone could be detected upon sounding the bladder. It was decided to operate in order to relieve the cystitis. The usual lateral incision was made in the perineum, and the bladder opened; at once a mass was exposed, which, when removed, would fill two or three tablespoons, consisting of small fibrinous tubes (like vermicelli) coiled in a mass and containing phosphatic deposits. The source of the fibrinous material was believed to be the right ureter, the tubes being casts of the ureter. There had been some evidences of kidney disturbances, and pain in the right loin. After the bladder had been evacuated, the patient made a rapid and complete recovery.

— The ex-resident physicians of the Pennsylvania Hospital formed a Society and inaugurated a series of annual meetings last month. There were several papers read at the meeting devoted principally to reminiscences of former triumphs, and to the growth of the institution. The managers have directed that the paper read by Dr. Morton [1] shall be printed in an enlarged form, with a number of phototype illustrations, and it is proposed to include the other proceedings of the meeting.

— Dr. T. A. Emmett, of New York, paid a short visit this week, and upon invitation of the Philadelphia Obstetrical Society delivered a clinical lecture at the Jefferson College Hospital, demonstrating his operation for uterine prolapse.

— The classes at the college are considered large and the clinics are well attended.

Miscellany.

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

IN our remarks last week upon the subject of polyclinics we inadvertently omitted to mention the post-graduate medical school and hospital of New York, which was one of the first institutions in this country to organize a scheme of instruction entirely for graduates in medicine. The completion and occupation of a new hospital building easily accessible to the large hospitals of the city has placed abundant clinical material at the disposal of the school and the corps of teachers comprises gentlemen abundantly able to utilize to the best advantage the material thus afforded.

RESPONSIBILITY OF APARTMENT-HOUSE LANDLORDS IN CASES OF BAD PLUMBING.

CONSIDERABLE interest has been manifested in a decision recently rendered by a court in New York, says the *Sanitary Engineer*, which, in effect, holds that when, by reason of inefficient plumbing, sewer-gas is permitted to enter an apartment in an apartment-house, the tenant may vacate and surrender the premises, and thereupon be relieved from his obligations to pay rent accruing thereafter. This is not an entirely new doctrine. The law in this particular respect has long been established. It was merely the application of a well-known principle of law to a new state of facts, reaffirmative of the proposition that when a landlord evicts his tenant the obligation to pay rent ceases. This eviction need not be actual — that is, by physical force. It may be constructive, such as when the landlord, by acts or omissions, so violates his duty toward his tenant as to deprive him of the beneficial use of his premises and thus force him to leave, and it is an eviction none the less by reason of the method by which it is accomplished.

Ordinarily, the tenant of an entire house, having control of the pipes and sanitary appliances, when he detects sewer-gas, may, by suitable repairs, prevent its further escape, and it would be his duty to do so; but the case of a tenant in an apartment-house is very different. The escape of sewer-gas into his apartment in consequence of defects in the general plumbing arrangements of the house, could not be controlled by him; and when the landlord permits it, the law justly allows the tenant to vacate, and imposes upon the landlord the loss of his rent.

The decision is founded in common sense, and, therefore, in justice, and while it may provoke adverse criticism from a class of unscrupulous landlords or their agents, it must commend itself for general approval.

THE DIETARY OF THE POOR.

THOSE whom hospital-work or private practice brings into frequent contact with the poorer classes of society, remarks the *British Medical Journal*, editorially, must often have been struck with the exaggerated importance which they attach to drugs in the treatment of disease, and with their proportionate ignorance and neglect of all principles of diet. The somewhat sceptical attitude towards medicines now fashionable in the profession — but likely to be as passing a fashion as farthingales or chignons in the larger world — has to some degree, permeated the highly educated classes, but it has scarcely affected the lower strata of society. Here, indeed, the error is altogether on the other side, and a profound and almost superstitious faith in the efficacy of drugs is found hand in hand with entire obliviousness of the enormous effect of principles of diet and of sanitation upon the individual and upon public health. The practitioner will have little success amongst his poorer classes of patients if, in addition to the ordinary prescribing of medicines, he do not institute a searching inquiry into the question of diet, and insist that the number, hours, and character of the daily meals shall be at least approximated to a correct physiological standard.

The most flagrant errors in the question of food on the part of the poor arise largely from their entire ignorance of the relative dietetic value of the various arti-

cles of daily consumption. The value of fleshmeat is well appreciated by them, but often it is beyond their means, and the substitutes adopted in its place are too frequently ill-suited for the maintenance of nutrition. Milk and eggs are not correctly estimated by the poorer classes, and, in the large towns, they are difficult to obtain of good quality, and at a reasonable price. We trust the time will soon come when the English farmer will cease the vain struggle to compete with the wheat-growers of America and Australia, and turn his attention to dairy produce, for which he has every advantage of soil, stock, and proximity to the best markets in the world. This diversion of the efforts of the English agriculturist into their natural channel would lead to the cheapening of milk, butter, cheese, and eggs, and the effect upon the national health would undoubtedly be most beneficial.

Vegetables, although much in use among the poor on the score of economy, are not correctly estimated dietically by them, and no distinction is made between those which are poor in nutritive properties and such vegetables as peas and beans, which, from their richness in nitrogen, are well calculated to supply the place of animal flesh. Sir Henry Thompson, in his excellent little book on *Food and Feeding*, remarks: "As an illustration of the value of legumes combined with fat, it may be remembered how well the erbswurst supported the work of the German armies during the winter of 1870–71, an instructive lesson for us in England at the present moment. It consists of a simple pea-soup, mixed with a certain proportion of bacon or lard, and dried so as to be portable, constituting, in a very small compass, a perfect food, especially suitable for supporting muscular expenditure and exposure to cold." The same writer goes on to speak of the great nutritive value of haricots and lentils, and their small cost compared with the price of meat, which is not more nourishing. Considerations of economy apart, there are many reasons for thinking that, as a nation, the English are too great meat-eaters, and that a larger preponderance of nitrogenous vegetables in the dietary scale would tend to reduce the ravages of rheumatism and gout.

Oatmeal, whether in the form of oat-cake or of porridge, and fish are recommended as foods of special value to the poorer classes, and a strong and much needed word is spoken against the use of tea to the exclusion of nourishing food.

HYSTERICAL PARALYSIS WITHOUT CONTRACTURE.

DRS. P. MARIE and Sonza Leite give in *Revue de Médicine*, May, 1885, a short summary of seven cases of hysterical paralysis without contracture in women under M. Charcot's care in 1884. The conclusions reached are thus summarized in the *Practitioner*:— (1) In all the cases sensation and muscular sense are either diminished or entirely lost in the paralyzed parts. (2) The tendon reflexes show no constant characteristic; in three cases they were increased, in four diminished or lost. This result contradicts the hypothesis that is sometimes put forward, namely, that all hysterical paralyses, even if they have no visible contracture, yet show signs of a tendency to contracture by their increased deep reflexes. (3) The hemiplegic distribution of the paralysis is the commonest type, the monoplegic the rarest; M. Charcot finds the face never affected. Seeligmüller and Buzzard, however, claim to have seen hysterical paralysis of the face. (4) The origin in four cases out of the seven was "dependent on idea," as Dr. Russell Reynolds says. One woman got herpes zoster on the left side; movement was painful at first and she gradually came to think it impossible in the left arm and leg; by sudden pressure on the eyeballs she was rendered lethargic, and the lethargy passed into a somnambulic state in which she readily assented to the suggestion that she could move both sides equally; she was put through a series of exercises before she was awoke, and when awake she found herself rid of her paralysis. Another girl, whose father was hemiplegic and who was afraid of suffering as he did, brought on herself a hysterical hemiplegia. In several cases the special senses were unilaterally affected; hearing was lost by one ear, smell by one nostril, taste on one side of the tongue, the visual field of one eye was commonly contracted, and the appreciation of color in various ways rendered abnormal.

SUICIDE IN CHINA.

DR. A. HENRY in his report on Ichang in the medical reports of the Imperial Maritime Customs of China says in regard to suicide:

Suicide is very common in Ichang, and in the numerous cases where it takes the form of opium-poisoning I am frequently called on to supply an emetic. Mr Cockburn of the Scotch Mission, who has a dispensary here, has almost endless cases of this kind. The native remedy is a dose of wood oil, supplemented by charms and enchantments. Death is also sought by other methods, as drowning, hanging, and self-wounding. The incitement to commit suicide is generally of the most trivial nature; but then one must take into account the force of fashion and the strength of the imitative faculty. Merely as an indication of the astonishing prevalence of what might be termed an Ichang malady, I cite three cases which within a few hours came to my personal knowledge.

10th June, 1884.— A young girl, the betrothed of a mason in the employment of the Customs, was living in the house of her future father-in-law. On this day she broke a basin, and being scolded, went into an adjoining room and hanged herself. 2. Same day, a man living in the city, who had an altercation with his father, committed suicide by hanging. 3. Next day, a young man living in the city, also having had some dispute with his father, rushed to the river beach and inflicted some wounds with a chopper on his chin and on the throat over the thyroid cartilage. I saw him in the evening, but by that time the application of a piece of the skin of a chicken had stopped bleeding, and there was evidently no serious damage done. I did not interfere with this treatment. The case terminated favorably.

GOV. ROBINSON'S RECOMMENDATIONS TO THE MASSACHUSETTS LEGISLATURE ON PUBLIC HEALTH.

THE people have been signally blessed by exemption from the dread ravages of pestilence. Epidemic cholera, in its progress westward, has not reached the shores of our country, and the precautionary provisions made by the last General Court remain entire and efficient for the current year.

Much alarm was excited by the threatening and uncontrolled prevalence of small-pox in Montreal, between which and our large towns and cities a constant interchange of persons is going on. In response to my request, the secretary of the treasury, directed from Washington agents to be sent to the border line between the United States and Canada, with instructions to devise and enforce every practical measure to prevent the spread of the loathsome disease southward. Though in scattered places in our State there have appeared cases which could be traced directly to Montreal for their origin, no permanent foothold has been gained, and is now believed that the time of extreme peril has passed.

To take cognizance of the interests of health and life among the citizens of the Commonwealth; to make sanitary investigations and inquiries in respect to the causes of disease, and especially of epidemics and the sources of mortality, and the effects of localities, employments, conditions and circumstances, on the public health; to gather information in respect to these matters for diffusion among the people; to investigate contagious or infectious diseases dangerous to public health, when they exist or threaten in particular localities, and to adopt means to prevent the spread thereof, either independently or in co-operation with the local authorities; to prohibit and prevent the carrying on of offensive trades; to take cognizance of the interests of the public health relating to the sale of drugs and food and the adulterations of the same, and to make all necessary investigations and inquiries in reference thereto — these duties are so comprehensive and important that, in view of the public welfare, their direction and supervision should be intrusted to those whose learning, wisdom and experience furnish the highest qualifications, and whose obligations to the public do not require work in other departments equally exacting. No portion of the duties which I have described — and there are many more of kindred character, such as to determine the sanitary effect of the pollution of sources and streams of water, and of the use of certain kinds of illuminating and fluel gas — can be neglected with safety. It seems to me it would be unwise in the extreme to assign the work of the inspection of drugs and of milk and other food, for the detection and prevention of adulterations, to boards or officers who are not qualified by education or experience for such analysis or inquiry. Town and city officers may, it is true, do much to enforce the statutes relating to this subject, which so closely touches the health and life of the people; but it will not be safe to depend on them alone. Intelligence, vigor, courage and vigilance are needed in one general board or commission, whose jurisdiction is limited in territory only by the boundaries of the State. The advantage of those who thrive upon the fraud and rascality of food and drug adulterations will be served by any action that shall obstruct or impair the enforcement of the law; but they have little reason to expect protection to their selfish interests.

I recommend the establishment of an independent board of health, which shall be charged with all the matters enumerated, and with others demanding like consideration and treatment. Such a board can work with entire harmony within itself, and would be relieved of the consideration of subjects foreign to the underlying principle of its organization. Medical and scientific men, sanitarians and specialists take a lively interest in the question, and from them a State board of health would receive most abundant aid, the benefits of which could not fail to reach the people.

I am aware how difficult it is — perhaps impossible — to discuss this topic without seeming to disparage or reflect upon individuals, but nothing is farther from my intention. Personal controversies, even about public affairs, may seriously concern the participants, but they are of little consequence when the problem is to determine upon a proper policy of administration. To transfer a portion of the work now imposed on the State Board of Health, Lunacy and Charity to another board of special creation carries no criticism or condemnation; it merely recognizes and removes the plain incongruity in duties assigned to the present organization. It can serve no useful purpose to rehearse the story of past differences or difficulties, and the triumph of partianship on one side or the other of such a question is of insignificant moment.

No elaborate legislation will be required to effect the change proposed, nor need the establishment of such new board materially increase expenditures. The present board will then continue to have supervision over the charities and lunacy. Inasmuch as the great body of lunatics are a public charge, they are proper subjects for consideration and control, in a large sense, by the charity department. As a rule, pauperism is a concommitant of insanity. There is, however, no similar relation or close connection between questions of sanitation, in the broad sense now outlined in the statutes, and the administration of public charities.

Exceptional instances will undoubtedly be met in the management of the health department which will call for the application of charitable relief, but no embarrassment can arise therefrom more than under the present system of apportionment of duties among several chiefs of departments, with sub-committees of the entire board supervising such work.

ACTION OF THE WORCESTER MEDICAL IMPROVEMENT SOCIETY ON THE DEATH OF RUFUS WOODWARD, M.D.

AT a special meeting of the Worcester Association for Medical Improvement, Dr. Leonard Wheeler offered these resolutions: —

Inasmuch as our good friend and comrade, Dr. Rufus Woodward, was suddenly taken from us by death, on Wednesday, December 30, 1885,

Resolved, that in him we have lost a brother practitioner of medicine, who has always commanded our respect, and in an unusual degree our love. That in his death we recognize a sad loss to ourselves and to the community which he served so long and so faithfully as a physician, devoted to his patients and to the public welfare.

Resolved, that in him we had before us a man of frank and manly virtue, a model of pure life and pure speech: one to whom we never appealed in vain for generous assistance or friendly sympathy.

Resolved, that we recall him as the first secretary of the organization, just forty years ago, and as one of its most constant attendants and firmest supporters ever since, and that we shall miss him sadly.

Resolved, that these resolutions be entered upon our records and that a copy be sent to his family, to the daily press, and the *Boston Medical and Surgical Journal*.

Dr. Sargent said: I had known Rufus Woodward longer than any one here present, and I presume that I knew him better. And now that he is gone I do not propose before this assembly of physicians to speak of him as a physician. Many of you can judge him in this capacity as well as I. It is of him as a friend and a man that I would speak. In friendship he was fast and constant. True himself, he was full of trust. My relations with him were too intimate and too tender for me to develop them here. In more than forty years of intimacy I never doubted him and never found him wanting. And as a man he was without guile. Of high principle and refined taste, and good culture, and manly dignity, he was superior to all the petty jealousies which so often poison the medical profession. I do not recollect ever having heard him speak an unkind word of any physician. And he judged all men charitably, rarely speaking of persons, but only of things. He had a love for his profession which was a part of his love of natural history, in which his proficiency was ever distinguished. His life was a happy one, for he studied constantly to add to the happiness of others. And it was happy especially because he was so happy in his home. There was never a tenderer and more devoted husband, and he took a fond interest in all that interested his children, enjoying their young life with them, and sharing in their amusements, in their studies, and in their occupation. He was no slave to money, and courted no applause. When we look back through his life, which was so pure, so earnest and so unselfish, we do not see the plodding and care-worn physician, but the good man, genial and lustrous in his golden atmosphere of good deeds and good cheer, and happy surroundings. If length of life is to be measured by the sum of happiness his life was long, and the lesson to us all is a good one.

Remarks were then made by Drs. Gage, Rice, Francis, Marble, Martin and others, Dr. Gage saying: —

Mr. Chairman: I have made no preparation for this occasion, and can add nothing worthy of the subject to what has been so well said. The very sad event which has occasioned this special

meeting has touched us all deeply. The death of Dr. Woodward is felt by every member of this association as a personal loss and bereavement. He was the friend of all and he was beloved by all. But to some of us who have known him longest and most intimately the shock of his sudden and untimely removal has come with a peculiar and an overwhelming force. To me, especially, who have known him familiarly ever since I came into Worcester County to live, who have always enjoyed his friendship, and who have lived by him in the closest of neighborhood relations ever since my marriage in 1860, it has come almost like the loss of a real brother. To observe him coming and going in unwearying response to the demands of a large and laborious professional practice, to receive his cheerful, robust and ever welcome greeting, and to spend with him as opportunity offered, when the work of the day was done, an hour of social intercourse and relaxation — these have been among the pleasant and almost constant features of my daily life for nearly thirty years. In removing him death has come very near to me and mine. Dr. Woodward was a good physician; an intelligent, upright and conscientious practitioner. His heart was full of tenderness and of kindly, manly sympathy with human suffering. His profession was with him a sacred trust, and he administered it as such. Multitudes who only knew him as the good physician will long and sadly mourn his loss. But as Dr. Sargent has well said, he was much more than a good physician. In the broadest sense he was a good man, a good son, husband, father, brother, friend and neighbor. He was a good and eminently useful citizen, wise, public spirited and helpful in every good work. He was, indeed, a true hearted and faithful man in all the relations of life. It is eminently proper and fitting, Mr. Chairman, that we should place upon our records, where it may be read by those who come after us, a suitable testimonial of the love and esteem in which we held our deceased friend, and I desire to express my hearty concurrence in the sentiments so appropriately expressed in the resolutions offered by Dr. Wheeler, and to adopt as my own the very just estimate of Dr. Woodward's character which Dr. Sargent has drawn in the remarks he has just read, and I now move you that both the resolutions and the remarks of Dr. Sargent be accepted and adopted as the sense of this meeting.

Correspondence.

EXPLORATORY INCISIONS OF THE ABDOMEN.

NEW YORK, 13 East 34th St.,
JANUARY 10, 1886.

MR. EDITOR, — On page 14 of your issue of January 7th, in the report of some remarks upon exploratory incisions of the abdomen, I am reported as saying that I thought simple opening of the peritoneum was as safe as sewing up the cervix uteri.

If such were my words I beg to amend them. What I attempted to say was, that *now* I opened the peritoneum, with as little apprehension as I felt *five years ago* in operating upon a cervix. This I said to emphasize the vast gain to abdominal surgery, which has been gained by simple but exact cleanliness.

Before the application of "Listerism" to gynæcology, cervix operations were often followed by pelvic peritonitis, and occasionally a case died. To-day any inflammatory reaction after such an operation is very rare. In fact in the hands of one familiar with the use of instruments, it has become one of the safest operations. Therefore it would be worse than misleading in one to say that incision of the peritoneum, no matter how great the case, was as safe as sewing up a cervix. Even *now* it cannot be said to be as safe as *was* sewing up a cervix five years ago, before the application of "Listerism."

In using my expression I gave vent to a personal feeling rather than to what I should lay down as a principle of action.

By giving place to this statement you will confer a favor upon me. Respectfully yours, W. M. POLK.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 2, 1886.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Diarrhœal Diseases.	Typhoid Fever.	Diphtheria and Croup.

Deaths reported 1,934: under five years of age 655; principal infectious diseases (small-pox, measles, diphtheria, and croup, whooping-cough, fevers, and diarrhœal diseases 296, consumption 289, lung diseases 256, diphtheria and croup 156, diarrhœal diseases 30, whooping-cough 26, scarlet fever 26, typhoid fever 21, erysipelas nine, malarial fever nine, cerebro-spinal meningitis eight, puerperal fever five, small-pox two, measles two, typhus fever two. From scarlet fever, New York six, Philadelphia four, Boston and Baltimore three each, Cincinnati, District of Columbia and Lynn, two each, New Orleans, Providence, Fall River and Salem one each. From typhoid fever, Philadelphia six, New York, Boston, Baltimore, District of Columbia and Lowell two each, Providence, Nashville and Chelsea one each. From erysipelas, New York five, Boston two, Philadelphia and New Orleans one each From malarial fever, New York four, New Orleans two, Philadelphia, Baltimore and District of Columbia one each. From cerebro-spinal meningitis, New York four, Boston, Nashville, Lowell and Fall River one each. From puerperal fever, Philadelphia, Baltimore, New Orleans, District of Columbia and Providence one each. From small-pox, New York two. From typhus fever, New York two.

In 107 cities and towns of Massachusetts, with a population of 1,257,737 (population of the State 1,941,465), the total death-rate for the week was 18.18 against 15.63 and 15.29 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,906,446, for the week ending December 19th the death-rate was 23.0. Deaths reported 3,918: infants under one year of age 855; acute diseases of the respiratory organs (London) 503, measles 140, whooping-cough 124, fever 49, scarlet fever 43, diphtheria 30.

The death-rates ranged from Brighton 16.4 to 41.2 in Plymouth; Birkenhead 18.5; Birmingham 22.7; Bradford 18.5; Hull 20.7; Leeds 23.8; Leicester 21.5; Liverpool 26.8; London 22.0; Manchester 26.5; Nottingham 33.8; Sheffield 23.2.

In Edinburgh 23.3; Glasgow 25.9; Dublin 34.4.

For the week ending December 19th in the Swiss towns, there were 43 deaths from acute diseases of the respiratory organs, diarrhœal diseases 24, diphtheria and croup nine, whooping-cough and typhoid fever each three, small-pox and scarlet fever each one.

The death-rates were: at Geneva 13.2; Zurich 13.6; Basle 17.4; Berne 26.2.

The meteorological record for week ending January 2d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 2, 1886, TO JANUARY 8, 1886.

GODDARD, CHAS. E., major and surgeon. Died at Fort Yates, D. T., January 4, 1886.

MUNN, CURTIS E., assistant surgeon and captain. Ordered from Department East to Department Columbia.

SHANNON, WM C., assistant surgeon and captain. Ordered from Department Platte to Department East, S. O. 4, A. G. O., January 6, 1886.

MCCAW, W. D., assistant surgeon and first lieutenant. Relieved from duty at Fort Lyon, Col., and ordered for duty at Fort Leavenworth, Kan. S. O. 1 Department of Missouri, January 4, 1886.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. OBSTETRIC AND GYNÆCOLOGICAL SECTION. — There will be a meeting of this Section at the large Medical Library Room, 19 Boylston Place, on Wednesday evening, January 20th, at 7.45 o'clock. Communications: Dr. J. E. Kelly, "Remarks on the Phenomenon of Vomiting in Pregnancy." Dr. E. W. Cushing, "Exhibition of Preparations of Septic Bacteria, with Observations on Puerperal Septicæmia." Drs. J. P. Reynolds, A. D. Sinclair, W. E. Boardman, and H. C. Ernst, will take part in the discussions. Refreshments after the meeting.

JAMES R. CHADWICK, M.D., *Chairman.*
ROBERT B. DIXON, M.D., *Secretary.*

DEATHS.

Died in Boston, January 6, 1886, James Henry Whittemore, M.D., M.M.S.S., aged forty-six years.

Died in Ware, Mass., January 10, 1886, Ebenezer Coolidge Richardson, M.D., M.M.S.S., aged sixty-five years.

CASES OF PERICARDITIS TREATED WITH SALICYLATE OF SODIUM.[1]

BY SAMUEL L. ABBOT, M.D.,

Visiting Physician, Massachusetts General Hospital.

CASE I. Peter M., aged twenty-five; cigar-maker. Entered the Massachusetts General Hospital, March 3d, 1885. His health had been generally good with the exception of an attack of acute rheumatism which lasted five weeks, one year before. For seven weeks before entrance he had had more or less rheumatism with swelling of the joints, compelling him to pass much of his time in bed, to which he had been confined for nine days before admission to the hospital. At that time there was pain in most of the joints. Complexion sallow, tongue pale. The patient smokes to excess, but is temperate in the use of stimulants. Temperature 100.2°. Pulse 130, regular, rather small. There is no dyspnœa.

Physical examination shows cardiac dulness, from half an inch to the right of the sternum to, or slightly beyond the left mammary line. Pulmonic sound not accentuated, but reduplicated at times. A very faint systolic souffle is heard at the base. There is general tenderness of the joints and those of the left index finger are swollen. Urine normal. Salicylate of sodium was prescribed, twenty grains to be taken every two hours. Under this treatment the pain was kept in check until the 8th, the patient on the 7th being found at the time of the visit sitting up in bed reading. The temperature on the morning of the 4th, was 101.9°, and ranged between this and 100.8° on the morning of the 8th, with a pulse of 100. The record of this morning reads: "Above the second left inter-costal space nearly to the clavicle, a soft to-and-fro friction sound is heard. This becomes loud and rough over the base of the heart and diminishes gradually to the apex, where it disappears. A marked systolic endocardial souffle is heard at the apex. There is tenderness on pressure just below the ensiform cartilage but none over the heart. A rough impulse is felt in the third left intercostal space, where a slight pulsation is seen, but none is visible at the apex. Pulse regular, non-compressible. The patient complains of pain in both wrists and some pain in the cardiac region on full inspiration." Ten grains of salicylate of sodium were directed to be given every hour *pro re natâ*, and cantharidal collodion to be applied over the præcordial region; through misunderstanding, however, this was applied over a surface not more than two inches square, causing moderate blistering.

9th. Patient has slept well. Cardiac condition unchanged. Temperature, morning 101°, pulse 96, respiration 37, evening, 101.6°, pulse 106, respirations 38. Salicylate was continued.

10th. Patient has suffered from severe pain on full inspiration and in the region of the heart, which was relieved by a sinapism. There is some pain in the left shoulder. This pain was relieved in the afternoon but the cardiac signs remained the same. Flaxseed poultices were applied over the heart during the day. Morning temperature 100.9°, evening 101.8°; pulse A.M., 106, P.M., 112; respirations 33, 37. Treatment continued.

11th. Patient reported that he had had the best night for some time, and at the time of visit was free from pain. Cardiac signs the same. A dry cup was ordered to be applied over the heart for half an hour. Salicylate of sodium to be continued. Morning temperature 100.6°, pulse 100, respirations 37; evening temperature 101°, pulse 112, respirations 38.

12th. Patient has suffered much during the night from pain in the shoulders and over the heart, but at the time of visit is free from pain in the cardiac region; there is still some in the shoulders. On examination "only a trace of the friction sound" could be heard, about one inch above the apex and mostly with the first sound of the heart; the systolic murmur at the apex has nearly disappeared. Another dry cup was ordered. Temperature in the morning 100.6°, pulse 120, respirations 36; evening temperature 102.4°, pulse 120, respirations 38.

13th. Patient reported that he had had much pain in the cardiac region early in the night, but slept well afterwards, and was free from pain at the time of visit, The friction sound is again harsh and loud over the base of the heart, louder with the systole than the diastole. The area of dulness extends half an inch outside of the left nipple and one inch to the right of the sternum from the second to the fifth intercostal space. Apex beat in the fifth intercostal space inside of the left nipple, heard but not felt. Morning temperature 101.5°, pulse 108, respirations 38; evening temperature 101.8°, pulse 100, respirations 28.

14th. Sleep has been somewhat disturbed by pain in shoulders which was relieved at the time of visit. Pericardial murmur less harsh. Temperature during the day between 99.7° and 100°, pulse 100, respirations 28, 28.

15th. Patient has had some pain during the night but slept well. The record says "The pericardial friction sound has wholly disappeared and there is now no increase in the normal area of cardiac dulness." Morning temperature 99, pulse 100, respirations 23; evening 100.6°, pulse 100, respirations 23.

16th. Has slept well. Some return of pain in the joints to-day. "No pericardial murmur. Endocardial murmur less loud." Temperature in the morning, 100.7°, pulse 94, respirations 24; evening 99°, pulse 94, respirations 23.

18th. Only endocardial souffle detected is a slight prolongation of the first sound at the base. A little pain in the outer left pectoral region to-day. Temperature in the morning 99.2°, pulse 84, respirations 32; evening 99.8°, pulse 86, respirations 22.

19th. Patient quite free from pain. Appetite good. Temperature in the morning 99.8, pulse 80. Evenning 98.7°, pulse 80, respirations 20, 19. The salicylate of sodium was omitted and a pill of two and a half grains of salicylate of cinchonidia, to be taken every three hours, was ordered instead. This was omitted on the 21st, on account of tinnitus, the patient sleeping well and feeling well. On the 23d, there was a slight return of the systolic souffle at the third left intercostal space with some pain and swelling of the joints, the temperature going up to 99.8° and 100°. The salicylate of sodium was resumed in the dose of ten grains every two hours *pro re natâ*. This gave speedy relief and the patient continued very comfortable until the 27th, the salicylate being taken as symptoms required. On this date the only sign of cardiac trouble was a prolongation of the first sound over the base. On the 28th, the temperature was normal for the first time. On the 31st, it was up a little, but there was

[1] Read before the Boston Society for Medical Improvement, January 11, 1886.

no pain. The salicylate was continued on account of the rise of temperature.

April 1st. The salicylate has been continued every two hours up to the time of the visit to-day. The temperature is now normal and there is no endo or exocardial murmur, and no sign of pericardial effusion; the sounds of the heart being normal and distinctly heard, and the area of dulness normal. On April 2d, the patient was discharged well.

The cardiac condition throughout the case may be summed up as follows: —

Possibly a moderate effusion in the pericardium on entrance, March 3d, with slight endocarditis.

8th. A pericardial friction sound heard for the first time over the whole cardiac region and transmitted nearly to the clavicle, with a loud systolic endocardial souffle at apex.

12th. The fourth day after the friction sound was first detected, only a trace of it could be heard, about an inch above the apex; the systolic souffle at this point had also nearly disappeared.

13th. Increase of pain, cardiac dulness and friction.

14th. Less friction sound, accompanied by a slight fall of temperature, it being 99°–100°.

15th. Entire disappearance of friction sound and of the increased cardiac dulness, the loud mitral systolic souffle having disappeared before.

18th. Only abnormal sound detected, a slight prolongation of the first sound at the base, possibly anæmic, which finally disappeared April 1st. Whole duration of friction sound seven days.

Case II. Anna A., a Swede, married, aged twenty-five, was admitted to the Massachusetts General Hospital, May 20th, 1885. Her general health had been good except for an attack of acute rheumatism in 1882, and a second in 1884: the present attack began three weeks before entrance. There had been general pain and joint swellings, and for the last four days considerable pain in the cardiac region. The patient had been confined to bed for a week. She had vomited occasionally and had had an uncomfortable feeling in the head with tinnitus, possibly caused by remedies which she had taken. The patient was well nourished and her color was good. There was swelling and redness of both hands.

Examination of the lungs gave a negative result. There was no increase of cardiac dulness. The apex-beat was in the fifth intercostal space inside of the nipple. A loud to-and-fro friction sound was heard over the heart, most distinct between the second and fourth ribs to the left of the sternum, indistinct at the apex. Pulse of good strength, regular, 82. Temperature 101.2°, respirations 28. Twenty grains of salicylate of sodium were given at intervals of an hour, three times, afterwards every second hour. Vomiting occurred at 6 P.M., accompanied by tinnitus and headache, and the remedy was given less frequently, but three doses being administered during the afternoon and evening. A suppository containing one-sixth of a grain of morphia was given in the evening. The temperature at this time was 100.2°.

21st. The patient was more comfortable. Morning temperature 100.8°, pulse 90, respirations 34.

Salicylate of sodium was ordered to be continued in the dose of twenty grains every two hours with half a drachm of aromatic spirit of ammonia in water. Six doses were taken during the day without any return of vomiting, with relief to the headache, but the tinnitus continued. There was no swelling of the joints and the patient was free from general pain while at rest: pain in cardiac region less, but the physical signs continued unchanged. The treatment was continued. Evening temperature 99.5°, pulse 72, respirations 28.

22d. Patient had slept most of the night, and had taken during the night three doses of salicylate, etc. She was very comfortable at the time of visit. The friction murmur was much less harsh than at first, and was heard loudest at the end of inspiration. The dose of salicylate was reduced to ten grains to be taken every second hour. Morning temperature 99.5°, pulse 72, respirations 30; evening temperature 98.6°, pulse 82, respirations 35.

23d. Patient very comfortable. Temperature normal throughout the day. Pulse 70 to 75, respirations 35 in the morning, 28 in the evening. Treatment continued.

24th. Condition the same. A dry cup was applied to the præcordia for half an hour and was followed by a single application of Tr. Iodinii Etherata to the same region. The salicylate was ordered to be given every hour, the aromatic spirit of ammonia to be given with each second dose. Morning temperature 98.6°, pulse 75, respirations 28; evening, temperature 98.9°, pulse 80, respirations 32.

25th. The patient feels very well, but still has some tenderness in the præcordial region on pressure. The friction sound is less marked and is heard over not more than one-half the area it has heretofore occupied. Morning temperature 98.8°, pulse 76, respirations 30; evening temperature 99.4°, pulse 90, respirations 28. Treatment continued.

26th. The friction sound has nearly disappeared but is still heard at the end of inspiration. There is no increase of cardiac dulness. No nausea nor tinnitus. Morning temperature 99.4°, pulse 88, respirations 29; evening temperature 99°, pulse 78, respirations 27.

27th. Friction sound heard only occasionally, at the end of long inspiration; disappeared entirely in the afternoon. Morning temperature 99°, pulse 79, respirations 27; evening temperature 98.3°, pulse 81, respirations 30. The dose of salicylate of sodium was reduced to fifteen grains, three times during the day, and the aromatic spirit of ammonia was omitted.

28th. General condition the same. No return of friction sound. Temperature normal morning and evening. Pulse in the morning 80, in the evening 72, respirations 29 and 25.

29th. Temperature normal, and the patient sat up half an hour. No endo or exocardial murmur can be detected. The salicylate was continued.

June 1st. A soft systolic murmur was detected in the third left intercostal space. The dose of salicylate was reduced to ten grains, three times a day, and in addition Tr. Ferri chlorid. m x. ter in die was prescribed.

2d. Patient doing well, salicylate omitted.

3th. Some complaint of pain in the left shoulder and the salicylate was resumed, ten grains to be taken every two hours *pro re natâ*.

On the 9th the record reads, "patient has been up and dressed for several days and feels well." The salicylate was omitted. On the 11th she went out of doors, and was discharged well on the 13th, without any abnormal cardiac signs.

The principal points in this case may be summarized as follows: —

Rheumatic attack of three weeks standing, with pain in cardiac region for four days before admission to hospital, on the 20th of May. Some cardiac friction sound detected without abnormal cardiac dulness. Salicylate of sodium given in full and frequent doses, causing vomiting with headache and tinnitus. Continuance of the salicylate with the addition to each dose of half a drachm of aromatic spirits of ammonia; — a remedy, I would remark in passing, which hardly ever fails to control the nausea and vomiting which so frequently result from the use of salicylic acid in its various combinations. Gradual diminution of the friction sound until its entire disappearance on the afternoon of the 27th, the seventh day of treatment, with gradual fall of temperature to normal. A slight anæmic murmur June 1st, which was treated with iron, and had entirely disappeared on the 11th, when the patient was discharged well.

It will be noticed that the salicylate of sodium was continued after the patient was free from pain and the temperature was normal, solely on account of the continuance of the friction sound,— a circumstance indicating the importance of a continuance of auscultation in these cases, even when the subjective symptoms do not seem to call for it. Its action was also kept up four days after the friction sound had disappeared. The exact duration of the pericarditis in this case cannot be determined, as the signs were present at the time the patient entered the hospital; but they disappeared in one week after that time. There was no evidence of pericardial effusion at any time.

CASE III. R. D., a woman, of middle age. This patient entered the Massachusetts General Hospital, April 12, 1885, suffering probably from a contracted kidney as indicated by the following history. For four weeks before entrance she had more or less headache, with frequent vomiting, vertigo, pain in the lumbar and dorsal regions. There had been dyspnœa for two weeks, during which interval there had been two or three convulsions. The eyesight was dim at times and the sleep had been disturbed. There had been no hæmorrhage and there was no œdema. Tongue dry and thickly coated. Pulse rapid, small.

On physical examination there was found cardiac dulness from the second right rib down to the fourth interspace, at which point it extended one and a half inches to the right of the sternum, the apex dulness extending to the mammary line. There was great tenderness over the lower cardiac area. A loud to-and-fro friction sound was heard over the base, which became distant and obscure at the apex. There were signs of œdema in the lower part of both lungs. There were frequent twitchings with tremulousness of the fingers and forearms; there was also a strong, somewhat urinous odor about the patient.

The patient's condition varied from hour to hour, and palliative treatment was employed; sinapisms were applied over the heart. Owing to the vomiting it became necessary to administer stimulants and milk with moderate opiates (Tr. Opii. deodoratæ m x) by enema. As an experiment, having in mind the two previous cases of pericarditis, on the 13th an enema was administered consisting of whiskey half an ounce, a raw egg, milk four ounces, in which was dissolved thirty grains of salicylate of sodium. This was ordered to be repeated every four hours, except that the salicylate was to be reduced in quantity to fifteen grains. Three of these enemata were given in all, their use being discontinued on account of the great distress which the necessary manipulations occasioned. They were followed by great exhaustion, the pulse being almost imperceptible. There was frequent twitching of the fingers and at times of the whole arm. The patient was quieted by an eighth of a grain of morphia.

Examination of the urine of the previous day gave the following result: urine pale; specific gravity 1007. A large trace of albumen; sediment in moderate amount, consisting of pus, large round cells and a few hyaline and granular casts.

On the 14th the patient said she was very comfortable, being free from pain. *No friction sound could be detected*, and the heart sounds were clear and distinct. Cardiac dulness as at first.

15th. The friction sound had returned and could be heard from the base half way down to the apex, and under the sternum to the ensiform cartilage. Sounds of the heart perfectly distinct. The salicylic enema was repeated, but a second was not retained.

16th. Patient mildly delirious, as she has been at times during the past two days. Salicin was given by the mouth, and five doses of ten grains each at intervals of two hours were retained, but their further administration was checked by vomiting. Urine of this day twenty-six ounces; specific gravity 1012; pale; a large trace of albumen. Sediment considerable, containing numerous hyaline, fine granular and waxy casts, many of large diameter, and pus.

17th. Cardiac dulness diminished, extending from the third rib down one inch to the right of the sternum, and nearly to the left nipple. Respirations ten, deep, irregular. Muscular twitchings continue. No urine passed voluntarily; seven ounces drawn by catheter at 6 P.M.

18th. Patient gradually failed and died at 8.40 P.M.

Temperature on the morning of the 13th, the day when the salicylate was given by enema, 100°, in the evening 98.2°. It rose to 99° the next morning, was normal in the evening, a little below the next day, and normal on the 18th, the day of her death. The urine varied in quantity from thirty-two ounces on the 13th to fourteen on the 17th, and eight on the 18th. An autopsy could not be obtained.

In this case there was no way of determining the duration of the pericarditis, as the signs existed at the time the woman entered the hospital; the friction sound, however, disappeared entirely after the first day's treatment by salicylate of sodium, to return after the treatment was discontinued. The patient's condition from her renal disease prevented its resumption.

CASE IV. A young lady eighteen years of age, seen in consultation in March, 1885, with Dr. Fuller of Charlestown. She had been suffering for a week with severe acute rheumatism, and at the time when I saw her had marked pericarditis of several days' standing. She was sitting nearly upright in bed, with quick pulse, great dyspnœa and high temperature. I regret that I have not exact numerical data of these conditions. There was extreme cardiac distress, and the region of the heart was so sensitive as not to bear percussion. A loud friction sound was audible throughout this region. She was taking at the time a moderate dose of salicylate of sodium three times a day, having been under salicylate treatment from the outset of her illness, and been actively treated locally by leeches, blisters, etc. At my suggestion larger doses of the remedy were given at short intervals, and as I subse-

quently learned from her physician, with marked benefit in twenty-four hours, and total relief in forty-eight hours; at which time there was no friction nor evidence of effusion, and the sounds of the heart were normal.

My apology for offering these few cases of this formidable cardiac affection is its comparative rareness in acute rheumatism since the specific salicylic acid and its compounds came into general use, and the fact that it is still generally regarded as one of the most intractable affections of the heart; likely to be, if not in its immediate results, certainly in the possibility of grave disability afterwards, one of the most serious.

I think I am justified in saying that at the present time all grave cardiac complications in acute rheumatisms are much less frequent than formerly; certainly this has been my own experience, strongly sustaining the hope and expectation which the first use of the salicylic remedies was calculated to encourage, that in the time to come their use would prevent the development of a very large proportion of these grave cases. A single fact gives great force to this conviction in my mind. During my four months service in the Massachusetts General Hospital in the spring of 1875, the year before Traube first recommended salicylic acid as a remedy for acute rheumatism, there were four deaths in my wards, of rheumatic patients, from pericarditis, with high temperature and coma. Since that time, a period of ten years, in the record of one hundred and eighty-four cases of acute rheumatism in all, in my service, I find the history of but eight cases of pericarditis. Of these one entered with this affection and remained three months, the physical signs having disappeared when he was discharged. No specific treatment was employed. A second also had pericarditis on entrance, the signs clearing up sixteen days after, but not disappearing so as to warrant his discharge until a month from that time. No specific treatment. The third entered with friction and effusion which continued for twenty-three days, when he was discharged. No specific treatment. The fourth had been ill two months on entering the hospital, with great effusion, and died on the second day after. In the fifth, pericarditis appeared several days after entrance, with rheumatic bronchitis, and the friction sound continued until his discharge four weeks later. No specific treatment. The sixth entered moribund with pericardial effusion and died the same day. No treatment. The remaining two cases are reported in this paper. In speaking of the majority of these cases as not having had specific treatment, I mean that the ordinary salicylic treatment which they all had, was not pushed with special reference to the cardiac affection. I cannot help thinking that the fact that there were no deaths among them, except the two that entered at the point of death, is significant as showing that the severity of the attack was probably modified by the previous treatment for rheumatism.

It would seem *a priori* that such remarkable specifics as salicylic acid and its compounds are for the inflammation and pain of acute rheumatism, should control all the symptoms which may ordinarily manifest themselves in its course, including the cardiac affections, which are as much a part of the attack as the joint pains and inflammation. In fact, they may be the first manifestation of it. And yet this conviction does not seem generally to have struck the medical mind.

With regard to pericarditis, I need hardly say that all Systems of Medicine regard it as the gravest possible complication in acute rheumatism; and yet even the latest authorities have little to offer to combat it but the old weapons of bleeding and blistering, digitalis, and other palliatives; no value being attached to the salicylic specifics. Thus Bramwell, in his admirable treatise on Diseases of the Heart and Thoracic Aorta, p. 339, American Edition, 1884, in speaking of the treatment says: —

"The treatment appropriate to the primary affection must, at the same time be persevered with. There is, however, one very important exception to this general rule, namely, that in rheumatic cases the further administration of the preparations of salicin, more especially salicylate of soda (for, according to Dr. Maclagan, salicin itself does not depress the heart), should be dispensed with. The diet should be light and nutritious, consisting chiefly of milk and soup."

Dr. Da Costa also, in his valuable contribution to the third volume of Pepper's System of Practical Medicine, on Diseases of the Pericardium, in speaking of the treatment of pericarditis, says: "but here let me at once record the more than uselessness of the salicylates. They have no influence when pericarditis has arisen, and if salicylic acid or its compounds are being given they should at once be stopped. The alkalies have a far better action." And in the discussion on rheumatism at the last meeting of the British Medical Association, reported in the Medical Record of September 5th, 1885, it was claimed that salicylate of soda has no effect on the cardiac complications of this disease.

Although the cases I have offered are too few to generalize from, I cannot resist the conviction that the rapid disappearance of the symptoms and the remaining sound condition of the affected organ are due to the power of the remedy employed. It may be said that these were mild cases, likely to be amenable to treatment. So far as the sufferings of the patient and the indications of fever are concerned this may be said to have been true to some extent of the first two, but certainly not of the last two. But why were the first comparatively mild? I cannot help thinking it was because they had been under salicylic treatment for rheumatism from the first, and that the attack of pericarditis was essentially modified by its influence. The latter two were severe, yet in these the disappearance of the physical signs was even more prompt than in the others. I cannot believe that the local treatment employed in the first two cases had any material influence on the result. It was certainly not of a very active character, and was used mainly for a palliative purpose. In the fourth case the most active local treatment had given no relief. In neither of them was there any evidence of constitutional depression caused by the treatment except in the third, the case of advanced Bright's disease.

It is an interesting question what was the condition of the heart which caused the friction sound in these cases. There has been much discussion on the general subject, some writers claiming that a simple dryness of the pericardium may be sufficient to cause it; others contending that the surface must be roughened by an effusion of lymph. The cause is likely to vary in different cases, and perhaps may not have been the same in all of these now reported. In the first there was no serous effusion detected at any time, but it is

impossible to say how long the friction sound had existed before the patient came under observation. If it had existed several days there may have been a deposit of lymph, although the likelihood that the patient may have taken salicylic acid in some form makes this point uncertain. At any rate the complete disappearance of this sign in a few days, without any evidence of adhesion or serous effusion remaining, would seem to show that the remedy employed possibly has the power of causing absorption of even this refractory product of inflammation. In the second case the varying intensity of the friction murmur would seem to indicate as its cause something of a more transitory nature. If the experiment is tried of rubbing the finger across a dry window-pane no sound is elicited; but the slightest moisture on the finger will at once bring out a creaking sound of friction. Is it not possible that a very slight exudation of serum on the surface of the pericardium may develop a similar sound in the same way? In the third case the friction sound disappeared within a few hours for an entire day — a result hardly likely to have occurred if the cause were not of a nature to undergo a very rapid absorption.

It was my purpose in following the treatment employed in these cases to push it to the extreme of endurance on the part of the patient, feeling that risk of injury from it was far less than that from unchecked pericarditis.

SIX SUCCESSFUL CASES OF OVARIOTOMY.

BY J. G. PINKHAM, M.D., OF LYNN.

THE operations described below occurred consecutively during the year ending with the date of the last case. With the exception of one fatal case previously reported, these are all the ovariotomies that it has fallen to my lot to perform.

In the management of each case, an attempt was made to carry out the general principles of antiseptic surgery with the most scrupulous exactness. Instruments, sponges, the hands of the operator and his assistants, all things, in fact, that could, by any possibility, become the bearers of contagion, were thoroughly cleansed and disinfected. The carbolic spray was used in the room, but was not allowed to play directly upon the wound. The strength of the carbolic solution employed in the atomizer was two and a half per cent.; for instruments and hands, five per cent.; for sponging abdominal cavity and wound, not more than one-half per cent. Lister's dressings were applied, and over them, several layers of sheet-cotton, broad strips of adhesive plaster, and a flannel bandage. The incision through the abdominal walls was made in the median line, and as short as was thought to be consistent with a speedy and correct performance of the operation. Great care was taken to stop all bleeding as it occurred. To effect this, I used in imitation of Dr. Homans, Langenbeck's serres-fins, with strings, and pieces of sheet-lead attached to keep them from getting lost in the abdominal cavity. When necessary, ligatures of catgut, or fine silk, were applied. The pedicle, when any existed, was tied with braided silk in two portions. It was then cut short, held with Dawson's clamp, and the end seared with Paquelin's Thermo-Cautery.

Great care was taken to cleanse the peritoneal cavity of blood, and of cystic fluid, when, by chance, any of the latter had escaped into it during the operation. The wound was closed by deep sutures of silver wire, which included the peritoneum, and by superficial ones of silk, when these were necessary, in order to bring the cut edges of the skin into exact apposition. As a matter of convenience, the operations were all, with one exception, performed upon a Crosby bed, the patient being allowed to remain upon it during the after treatment. No nourishment was given, as a rule, for twenty-four hours or more after the operation, but stimulants were employed *per rectum*, when needed. As an anodyne, reliance was placed mainly upon suppositories of bimeconate of morphia, as this agent had been found, in my hands, to produce less unpleasant after-effects than most other opiates. In these operations, I have had the assistance, at different times, of Dr. Wm. G. Wheeler, of Chelsea, and of Drs. Lovejoy, Emerson, Colman, Sheldon, Stevens, and Little, of Lynn. I feel myself under obligations to all these gentlemen, more particularly to Dr. Lovejoy, who placed two of the cases in my hands, and helped me materially with all; and to Dr. Wheeler, without whose wise counsel, born of a large experience in ovariotomy, it would have been much less easy for me to extricate myself from the difficulties presented in the third and fifth cases.

CASE I. Mrs. M., aged thirty-seven, a shoe-stitcher by occupation, consulted me in June, 1884. She was married, and had two children, aged respectively, twelve and fourteen years. At the age of twelve, she had scarlatina, among the persistent sequels of which were impaired hearing, and a tendency to diffused spasm of the facial muscles. Menstruation was generally regular, and normal in amount; but occasionally, there was a delay of a week. Urine normal. Patient anæmic, and subject to fainting spells, with a partial loss of consciousness. On examination, the lower part of the abdominal cavity was found to be occupied by a well-defined, fluctuating mass, which extended nearly to the umbilicus. According to patient's statement, the abdomen had begun to enlarge something more than a year before, but the greater part of the increase in size had taken place within the preceding six months. As all the physical signs of an ovarian cystoma were present, the diagnosis was made without difficulty. Removal was advised after a short course of tonic treatment.

The operation took place on the 19th of September, 1884, at the patient's home in Lynn. Incision two and a half inches in length. The tumor proved to be an oligo-cyst, without adhesions. Weight, five and a half pounds. One of the small cysts had been ruptured previously to the operation, and its semi-solid contents were sponged out of the abdominal cavity. The walls of this cyst were very thin, and it is not improbable that the rupture occurred while the patient was being moved just before the operation. Pedicle long. Other ovary healthy. Wound closed by four deep, and three superficial sutures. The patient bore the ether well, and rallied promptly after the operation. At 4 P. M., five hours after operation, vomiting took place, attended by a slight collapse, as a result of the nausea. This soon passed off. During the first night, there was a little pain, which was quieted by a rectal suppository, containing one-quarter grain bimeconate of morphia. After this, no anodynes were required. About six hours after the operation, the temperature rose to 100.5° F., but four hours later, it had fallen to 99.8°,

and never afterwards reached 100°. No nourishment was given until the morning of the second day. Convalescence proceeded without interruption, or notable incident. The superficial sutures were removed on the seventh, and the deep on the ninth day. In three weeks, the patient was able to sit up, and soon afterwards, to move about the house. She has been in an improved state of health since, and is now engaged in her old occupation of stitching shoes.

CASE II. Miss M. E. C., aged twenty-four, shoe-stitcher. Father a paralytic; mother dropsical. Had one brother who was healthy. Her own general health had been fair. She first noticed the tumor in July, 1883. Had no unpleasant sensations, except slight pain, and "a sort of prickly feeling" in the left leg. Menstruation irregular. Amount normal. Bowels regular, and appetite good. No change had been noticed in character or amount of urine. Heart, lungs, and kidneys healthy. Admitted to Lynn Hospital, October 7th, 1884. Operation, October 8th, at 11 A. M. Incision two and a half inches in length. The tumor proved to be a monocyst, weighing, with its contents, fifteen pounds. Pedicle long. No adhesions. Wound closed by five deep, and four superficial sutures. Vomiting occurred only once. The temperature never rose above 100° F., and there was no interruption to convalescence, except that on the twelfth day after the operation, menstruation occurred, accompanied with pain and swelling of the left leg, and a rise in temperature (99.°5 to 100°). These symptoms subsided in a few days. The wound healed throughout by first intention. At the end of four weeks, the patient left the hospital in fair health. She has since become fleshy and robust looking, and has returned to her former occupation.

CASE III. This patient was placed in my hands by Dr. Francois, of Saugus. She was a married woman, thirty-five years of age, who had formerly worked in a shoe-shop, but was at that time doing her own housework. She had never borne children, but had miscarried once shortly after marriage. Menstruation began in her twelfth year, and was regular up to the thirty-first year, at which time it became more frequent, the intervals varying from one to three weeks in length. Amount at each period normal. At the time of my first visit, December 10, 1884, she was just recovering from an attack characterized by gastric disturbance, pain and tenderness over the duodenum, frequent micturition, and considerable elevation of temperature. She stated that she had been subject to such attacks for several years; otherwise her general health had been good.

Some six years before she had noticed a small lump in the right ilio-hypogastric region. This increased slowly and in three years was as large as a child's head. At that time she consulted an eclectic physician who tapped the tumor, and drew from it a dark fluid, looking like molasses and water. Six weeks later he tapped again, and subsequently, injections were made into the sac with the purpose of effecting its obliteration. In two years the tumor was as large as before the tapping. After this it increased to some extent in size. On examination it was found to occupy the hypogastric and right iliac regions, and to extend obliquely upwards towards the right, through the umbilical into the lumbar region. It was somewhat movable from right to left but seemed fixed above and below Fluctuation distinct throughout. Contour uniformly rounded. There was an area of tympanitic resonance to the right of and above the tumor. By the vagina the growth could not be felt occupying any part of the pelvic cavity. The uterus was retroverted, and not notably enlarged. The urine was found to be acid and slightly albuminous. Its specific gravity was 1020. It contained an excess of earthy phosphates, and, as seen by the microscope, pus in considerable quantity, vaginal and vesical epithelium and bacteria, but no renal casts. The nature of the tumor in this case seemed doubtful, but a careful consideration of all the facts presented, led to the conclusion that it was an ovarian monocyst with extensive adhesions fixing it to the right side. An immediate operation for removal was advised, with a guarded prognosis as to the result. Operation January 8th, at a room procured for the purpose in Saugus Centre. Drs. Wheeler, Lovejoy and Francois were present and assisted. Incision in the median line midway between umbilicus and pubes, about three inches in length. The tumor thus disclosed was shown to be covered by an extremely vascular envelope, which, when followed to its connections by the hand passed within the abdominal cavity, appeared to be continuous on all sides with the peritoneum. No pedicle could be discovered, and the mass was no more movable at its upper than at its lower end. There were slight adhesions of the vascular covering to the parietal peritoneum at the site of the old punctures. The cyst was evacuated by a small trocar and canula. Fluid dark colored, hæmorrhagic, somewhat viscid. At Dr. Wheeler's suggestion the finger was thrust through a thin place in the covering of the cyst, high up, a strip of the same separated, tied in two places, and cut between the ligatures. This process was repeated on each side of the opening until the empty sac could be drawn out. The remaining portion of the envelope was then treated like an ordinary pedicle. No blood to speak of was lost in thus dealing with the vascular covering of the tumor. The tumor was a monocyst of which the lining membrane showed a distinct papillomatous structure. Wound closed by five deep and five superficial sutures. The patient had unfortunately taken some milk contrary to advice just before the operation. As a consequence she vomited while under ether, and several times on coming out from under its influence. The usual course of after-treatment was pursued, but for the first week the stomach was so irritable that it was found necessary to nourish the patient almost wholly by enemata. The injection consisted of a gruel made of Bartlett's pepsinated nutriment, with Valentine's meat juice, and brandy. A little deodorized tincture of opium was given with the enemata, when necessary to allay pain and procure sleep. Soon after the operation the abdomen became very tympanitic, so much so as to produce a decided tension upon the sutures. On the eighth day the patient took and retained a little koumiss. As there was a marked redness about the sutures they were removed and the wound secured by numerous long strips of adhesive plaster. On the ninth day menstruation began. Vomiting had occurred once and the bowels had moved spontaneously during the night. On examining the wound it was found to have reopened to the extent of an inch and a half in the central portion, and a dark, liquid, looking like the product of a broken down blood clot, to have escaped, to an estimated amount of two drachms. The plaster was reapplied and the edges of

the gaping wound drawn together, an opening being left for drainage.

From this time on for a period of about three weeks the history of the case, which it would be tedious to give in full, was that of a mild septicæmia, characterized by an irregular temperature, scarcely ever rising above 101° F., by occasional chilliness, sweating, nausea, and diarrhœa, by an attack of sub-acute pleurisy on the right side at one time, and by pain and swelling of the left leg at another. The treatment was directed mainly to supporting the patient's strength. She took by the mouth such delicate nourishment as she could retain, with light stimulants; by the rectum, when diarrhœa was not present, the enemata mentioned before and quinine suppositories. The wound was dusted with iodoform and dressed with tarred oakum. It filled up slowly with granulations and healed.

The wound was, in my opinion, the source of the septicæmia. There was no evidence at any time of peritonitis. After the wound reopened a portion of the omentum and intestine could be seen, and they were not reddened. There was no disposition manifested at any time to a hernial protrusion. It is not improbable that the whole trouble came from the milk which the patient took before the operation. She was subject to dyspeptic attacks, as before stated. One of these the ether caused by preventing the digestion of the milk. From this came the distension of the abdomen and the irritability of the stomach. The distention drew upon the wound, perhaps causing a little bleeding between the lips, and the formation of a clot, which afterwards breaking down was the source of the reopening, the septicæmia and the slow healing. As a result of all this the patient was eight weeks in getting well, instead of four, as might have been the case under other circumstances. She went to her home on the 10th of March, and has been in good health since.

CASE IV. Mrs. F., of Peterboro', N. H., housewife, aged seventy-one, was admitted to Lynn Hospital on the 24th of April, 1885. She stated that her abdomen had been enlarging for more than ten years. Her general health, however, had been pretty good, and she had not experienced much inconvenience from the growth, until it became so large as to trouble her by the weight and pressure. Her face and the upper parts of the body were much emaciated, but her eyes were bright and mind clear. Appetite and digestion fair. Urine normal. Heart and lungs sound. Abdomen very much distended; superficial veins prominent; ribs widely separated by the crowding upwards of the tumor. Diagnosis, ovarian monocyst. Operation for removal April 25th. The abdominal walls were found to be thin and the peritoneum dry and leathery in appearance. The tumor proved to be a monocyst, as was thought. Its contents were as clear as spring-water. Specific gravity 1010. The pedicle was on the left side and rather short. Uterus and other ovary atrophied, low down in pelvic cavity. No shock attended the operation, and but little fever followed. On the seventh day the superficial sutures were removed and on the ninth the deep. Wound firmly united throughout. There was a little redness around some of the suture points. The patient did well in every respect until the twelfth day. She then experienced a chill, and her temperature rose to 103° F. These symptoms were coincident with the occurrence of a light attack of erysipelas which began at the wound and spread slowly over a considerable portion of the front and sides of the body. It was of a mild type and did not cause vesication. The constitutional symptoms were not severe, there being no suffering, and nutrition not being notably disturbed. The temperature after the first day gradually fell and did not again rise so high.

The treatment consisted in the administration of quinine, malt, stimulants, and nourishing food, and locally to the wound iodoform, and to the inflamed surface beyond, a paste made of salicylic acid, alcohol and water. Convalescence was delayed for nearly two weeks by this occurrence. At the time of the outbreak there was a case of traumatic erysipelas in a remote part of the hospital establishment, and the disease was somewhat prevalent in the town as an idiopathic affection. A considerable discharge of pus took place from several of the suture holes during the progress of the erysipelas, and subsequently. On the 1st of June the patient was able to leave the hospital. She is now in the enjoyment of excellent health for a person of her years. The tumor weighed nearly sixty pounds, and the patient after its removal scarcely more. The history of this case, and the result of the operation show for what a length of time the system will tolerate a slowly growing monocyst without suffering serious derangements, and, also, what a marked power of endurance for surgical operations and for disease is sometimes possessed by aged people.

CASE V. This patient was first seen by me January 25th, 1885. The notes of the case as taken at the time are given below. "Mrs. C., aged forty-four, married. Has lived apart from her husband for the past five years. Has had four children, the youngest being now twenty years old. Had one miscarriage sixteen years ago. Menstruation began at age of sixteen. Always had considerable flow, never less than fifteen napkins, sometimes twenty-one. Always regular until six years ago, when she went three months without menstruating, and then came around as usual. Since that time she has been very irregular, the intervals varying from two weeks to several months. Sometimes the flow has been profuse, and once it lasted six weeks. She has now been six weeks over her time. Her father died an insane suicide at the age of fifty-two. Her mother died of 'dropsy of bowels.' Three sisters have died; two before patient's recollection; one insane. Three sisters are living; one has a 'tumor of the bowels,' another never menstruated, and is dropsical, the third one is well. The patient has a small tumor in the back, a lump of the size of a hickory-nut in the left breast, below the nipple, quite hard, movable. About seven years ago, she discovered an enlargement in the lower part of the abdomen nearly in the median line, which increased in size from that time forward. Five years ago she consulted a distinguished physician, who diagnosticated 'a tumor,' and advised against any attempt at removal. Some time later she saw another physician who thought the disease ovarian, and advised removal. Five months ago she put herself under the care of an eclectic physician, of Boston, the same one, in fact, who had treated patient No. III. He tried to cure by injections into the substance of the tumor. Since this treatment was begun, the tumor has seemed to grow faster than ever. The injections were given twice a week for two months. Patient never had any severe sickness, but is subject to a cough in winter. On examining the abdomen it is found to be irregular in con-

tour. On the right low down is a rounded, firm-feeling mass about as large as a cocoanut. On the left is a small rounded mass which seems to be solid. Above, fluctuation is detected, more distinctly in some parts than others. Percussion sounds tympanitic in both loins, and on left above the small, round mass, nearly to umbilicus, and downward (as patient lies on back), to the loin. Between the umbilicus and the ribs, towards the left is an area of tenderness. At this point injections were made, as, also, into the hard mass on the left below. On digital examination the pelvic cavity is found completely filled with a solid-feeling mass which gives no sense of fluctuation to the finger. The cervix uteri, reached with difficulty, is found high up, and far over towards the left. Bimanual examination indicates that the round mass in the left iliac region is the fundus uteri. Uterus moves when abdomen is pressed upon. After repeated trials cannot succeed in passing the uterine sound. It enters about one and a half inches, but beyond this point, on account of the extreme curvature required to reach the os, it will not go. The attempt causes quite a free flow of blood."

The history of this case and the physical signs seemed to point somewhat strongly to the diagnosis of uterine fibro-cyst. At my suggestion the patient consulted Dr. Wheeler, who thought the diagnosis doubtful, and advised aspiration to determine the nature of the fluid in the cyst. This was done on May 23d, the fluid proving to be brownish in color, and slightly sticky to the finger. Heat and nitric acid caused a dense coagulum to form, but no spontaneous change occurred on standing, except the deposit of a layer of sediment on the bottom of the bottle containing the fluid. Sp. gr. 1025. Under the microscope numerous ovarian corpuscles were seen, with granular matter, the debris of broken-down epithelial cells, and some blood. As a result of this examination, the tumor was decided to be ovarian, and an attempt at removal was advised. Operation at No. 10, Norcross Ct., Lynn, June 2d, 1885. Present, Drs. Wheeler, Emerson, Lovejoy, Colman, Stevens and Little. The tumor proved to be a multilocular ovarian cyst, bare and non-adherent above, below invested with an extremely vascular peritoneal layer, and closely adherent on all sides in the pelvic cavity, and to the uterus, which it had drawn up, and crowded far over to the left. The *fundus uteri* was, as supposed, the small round mass which had been felt above the pubis. The cyst was evacuated with an aspirator. From the large sac above, three quarts of brownish fluid, like that obtained before, were drawn. A smaller sac furnished a pint of milky-looking fluid. Several small loculi contained a clear liquid. The pelvic portion of the growth which had been thought to be solid, was found to have very thick and dense walls, and to be closely wedged into the pelvic cavity. The tumor was removed by laboriously separating the peritoneal layer with the finger in strips, tying in two places, and cutting between the ligatures, as in case III. Any hæmorrhage that occurred during the process was arrested for the time, by Pean's forceps, or the serres-fins, so that but a very trifling amount of blood was lost. The adhesions to the pelvic organs were so close that it was not thought safe to attempt to separate them. Hence the cyst wall itself was tied in sections and left. The pelvic cavity now being thoroughly cleansed, a glass drainage-tube of about one-half inch lumen, and slightly bent, was passed to the bottom of Douglas's fossa, and the abdominal wound, which was about three and a half inches in length, closed in the usual manner. One suture was passed below the drainage-tube, and the ends of the wire being tied around the tube, were made to hold it securely in place. The antiseptic dressing was applied as usual. The ligatures used were not counted, but it was thought that at least twenty were left within the peritoneal cavity. The patient bore the long operation well, being carefully watched by Drs. Emerson and Stevens, who attended to the administration of the ether, and gave a hypodermic injection of brandy whenever the flagging pulse of the patient seemed to indicate it. At 4 P. M., two and a half hours after the close of the operation, the patient had a pulse of 84, and a temperature of 99.6°. She vomited several times and had some pain, for which she was given a suppository containing one-half grain bimeconate of morphia. She remained fairly comfortable during that night and the following day, taking only a little ice by the mouth, and enemata of brandy, beef juice and pepsinated gruel. On June 4th, the wound was dressed for the first time. All the dressings were found saturated with bloody serum, which had escaped from the drainage-tube in great abundance. Patient suffered a good deal from thirst and nausea. On June 5th, she began to take milk and gruel. Flatus passed per anum. Menstruation began. Temperature in the morning 98.6°. In the evening she vomited and the temperature rose to 101°. The discharge from the tube began to be offensive. Wound dressed with carded oakum. As the history of the after-treatment of this case must be greatly abridged it will be sufficient to say that the patient was visited four times in each twenty-four hours. At each visit the wound was dressed, and the pelvic cavity cleansed. For this purpose a common piston syringe was used, a rubber tube being attached to the nozzle, by means of which all the fluid that could be reached was drawn out, and the cavity then washed out by a weak solution of chlorinated soda, carbolic acid, or boracic acid. Iodoform was occasionally dropped into the tube. The discharge, at first red, gradually lost its color, and in a week had began to show signs of pus. Later it became distinctly purulent. The sutures were removed on the eighth and ninth days. On removing the suture below the tube, pus escaped by the side of the tube, and ceased to come through it. On the seventeenth day the glass tube was removed, and a fenestrated rubber tube substituted. On the eighteenth day the patient was removed from the Crosby bed to an ordinary one. On the thirty-first day the tube was pushed out by an act of coughing. It was followed by a soft, grayish slough about as large as a man's thumb, several smaller masses of the same description, and an abundance of thick pus. The wound healed by first intention down to the drainage tube. During all this time the patient had a temperature varying from normal in the morning to 100° or slightly less in the evening. A few times it went to 101° or upwards, but soon fell to its usual range. Great care was taken to keep up the strength by suitable nourishment, stimulants, quinine, iron, etc. Notwithstanding the copious discharge of sero-pus, the patient improved steadily, but slowly. Only one ligature was known to have come away. At this date, about five months after the operation, the patient's health is fair, and she is able to be about the

house, and go out of doors, although there is still some discharge from the sinus. The uterus is in *situ naturali*, but is nearly fixed in position. There is some hardness of the vaginal roof on the right side of the uterus, but no mass of induration there. I think it safe to say that in this case the success of the after-treatment was due to the free drainage, which, with the frequent washing out of the pelvic cavity, prevented any notable amount of septic absorption, and the unremitting efforts made to maintain nutrition. I made upwards of two hundred visits to this patient. That she would die was, I think, the feeling at the close of the operation, of every gentleman present, except Dr. Lovejoy, who with characteristic hopefulness, expressed the opinion that she would "pull through."

CASE VI. Mrs. M., a widow, aged fifty, boarding-house keeper, consulted me in December, 1882, giving the following history of herself. She was first unwell at the age of thirteen. Menstruation had always been regular and normal in amount until the menopause, which occurred a few years before. She had one child, then twenty-seven years of age. Some ten years ago, while living in Wakefield, Mass., she consulted Dr. S. W. Abbott, who diagnosticated retroversion of the uterus, and an enlargement of the right ovary. A short time after this, she went to the New England Hospital for Women, and staid two months. She was told there that the right ovary ought to be removed. Acting upon advice received, she went back to Wakefield, and again placed herself under the care of Dr. Abbott, intending to return to the hospital in six months for the operation. At the end of that time, however, she was in so good a state of general health, that she abandoned her design. Has lived in Lynn for the past eight years. On examination, I found a firm-feeling tumor about as large as a cocoanut in the region of the right ovary. Uterus retroverted. Some months later the tumor was found to have increased notably in size, and to be manifest as a rounded mass above the pubes, with distinct fluctuation. On my advice she consulted Dr. Bixby, by whose suggestion I drew off some of the fluid of the cyst for examination, and sent it to him. The result of the examination was negative, and the doctor being at that time in doubt as to the nature of the case kept it under observation until January 1884, when tapping was resorted to. About twelve quarts of fluid, looking precisely like that of ascites, were obtained. This I examined, and satisfied myself that the disease was ovarian. After the tapping, no tumor could be felt, either by palpation of the abdomen, or by vaginal examination. The health of the patient improved after this, and the cyst refilled very slowly, so that it was not until the spring of 1885, more than a year subsequent to the tapping, that she would listen to my proposition for removal. Then she assented, but wanted to postpone the operation until October, or later. By the first of September, however, she had begun to feel so great an impairment of her general health, that she decided to delay no longer. She was still quite stout, but had wasted somewhat, especially about the chest and shoulders. The abdomen was larger than before the tapping. Operation at patient's home in Lynn, September 16th. Incision two and a half inches in length. Tumor an oligocyst with a solid portion at juncture of pedicle. The fluid of the largest cyst was dark brown, that of the smaller ones light colored. The solid portion was about as large as a coffee cup, and so hard as to suggest malignancy. There was one adhesion to the omentum, which required to be legated before it was divided. Weight of tumor and contents about twenty-five pounds. Wound closed by five deep sutures. The operation was well borne. On the second day the temperature went slightly above 100°, but on the third it fell to 99°. On the fifth day there was a slight disturbance of the stomach and bowels, caused apparently by some greasy beef-tea which had been taken, and the temperature again rose to 100°. After this it never went above 99°. The use of the catheter caused a little irritation of the bladder resulting in frequent calls for its evacuation. Apart from these incidents there was no interruption to the convalescence. At the end of three weeks the patient sat up, and is now attending to her household duties. The solid portion of the tumor has been examined by Dr. Colman, and pronounced malignant. As after the tapping in January 1884, no tumor could be found, it seems probable that this malignant growth was wholly secondary, and that it developed subsequently to the tapping. The long time that the ovarian disease in some form had existed would seem to give support to this view. The prognosis in such cases is not altogether bad, if we may accept the statement of Peaslee.[1] A lesson on the advisability of an early removal of ovarian tumors may be drawn from this case. The best time to operate is undoubtedly when the diagnosis is first made reasonably certain.

Hospital Practice and Clinical Memoranda.

CASES OF ANÆMIA.

MASSACHUSETTS GENERAL HOSPITAL.

SERVICE OF E. N. WHITTIER, M.D.

REPORTED BY CHARLES W. TOWNSEND, M.D., SENIOR MEDICAL HOUSE OFFICER.

IN the following cases of anæmia, blood counts were made, from time to time, with a Zeiss hæmatometer, kindly loaned by Dr. H. F. Vickery. In all the counts, the number of blood-corpuscles in the whole number of squares — that is, in one-tenth cu. mm. of the diluted blood — were counted, and, at least, two, sometimes four or more counts were made, and an average of all obtained. With two exceptions noted below, the counts were all made by the reporter.

In the first two cases, the diagnosis of progressive pernicious anæmia was made, although the improvement under treatment in the second case, may be thought, by some, to disprove it. In the first case, the presence of albumen and casts in the urine, might be thought to point to renal disease as the cause of the anæmia, but from the fact that the specific gravity and daily amount of urine showed no serious impairment of the kidneys, and from the fact that the anæmia was so extreme, it seems more probable that the diagnosis of an idiopathic, rather than of a secondary anæmia, is the correct one.

CASE I. The patient, Bridget A., entered the hospital, September 21st, 1885. Forty years old, unmarried, a domestic by occupation; born in Ireland. Family history good. Previous health generally good; had measles and whooping-cough when young, and ery-

[1] Ovarian Tumors, page 181.

sipelas two years ago. Catamenia previously regular; became scanty six months before entrance, and has been absent for four months. Six months ago, began to feel poorly, having a tired feeling in the hips and back. During this time, has vomited nearly every day after eating, the vomitus consisting of food and mucus. Head feels dizzy, especially on exertion, and she complained of a buzzing sound in her ears. Dyspnœa on exertion; slight cough, at times, without expectoration. Slight swelling of feet and legs for six months. Bowels inclined to constipation. No history of hæmorrhages from mucous membranes. Rapidly increasing weakness and loss of color.

On physical examination, the most noticeable point is the extreme pallor, the lips being nearly white. No emaciation, there being a very fair amount of subcutaneous fat. Slight œdema of feet and legs. Tongue clean and moist, but very pale and flabby; pulse rapid, regular, of fair strength. Nothing abnormal on pulmonary examination. Soft systolic murmur at base of heart. No enlargement of heart. Urine is yellow, acid, 1017, contains a faint trace of albumen; slight sediment of leucocytes, a few bladder and vaginal epithelium cells, and a few hyaline and fine granular casts, some with fat globules adherent. The twenty-four hours' amount of urine averaged ℥30, occasionally going as low as ℥20, and once as high as ℥80.

The bowels at first regular, with a tendency to constipation, became very loose during the last fortnight before death, averaging ten or a dozen dejections daily, not controlled by opiates. A dejection on November 5th contained a small amount of blood, this being the only hæmorrhage noticed in the progress of the case. The extreme pallor, gradually increasing, was, however, the marked feature, and the following blood counts, made with a Zeiss hæmatometer in the manner noted above, show the extreme anæmia. The counts showed no increase in the number of white corpuscles, and are as follows:

October 3d.	Average of	2	counts,	630,000	red corpuscles in 1 c. mm.
" 18th.	"	3	"	561,000	"	"
" 27th.	"	3	"	558,333	"	"
Novem. 1st.	"	5	"	536,000	"	"

The basis for comparison being from 4,500,000 to 5,000,000 red blood-corpuscles in one cubic millimeter of normal blood, we have here a diminution to nearly one-tenth of the normal number.

The temperature generally fluctuated between 99° and 100° F., once or twice reaching 101°. The pulse was always above 100, generally in the neighborhood of 120. Respirations from 25 to 30. The patient took a large amount of liquid nourishment, and retained her flesh till the last week before death, when she was able to take but little food, and rapidly emaciated. Iron and arsenic were given for a few days, but were omitted on account of vomiting, which was a very persistent symptom, and was, at first, treated with pilocarpine, on the supposition that it was uræmic, without effect. Morphia in suppository was found to be of the most use in controlling this symptom. Urine and faeces were passed involuntarily for two weeks before death, although the patient seemed conscious and fairly rational to the end.

During the last week, she tossed about and groaned loudly at times, but when questioned, said she was perfectly comfortable. Three weeks before death, the pulse was imperceptible at the wrist for three days, then appeared again feebly, to be absent for two days before death, which took place November 16th. The friends, unfortunately, refused an autopsy.

CASE II. Lucy R., fifty-five years old, a widow, entered hospital July 8th, 1885. History of phthisis, apoplexy and insanity in the family. Previous health generally good. Has had no children or miscarriages. Catamenia ceased five years ago. Had worked hard as a nurse, and had been feeling poorly for a year, and losing flesh and color. The patient entered with a mild attack of peritonitis, and shortly after, developed lobar pneumonia, from both of which she recovered in the course of a few weeks.

The chief points in the physical examination were extreme pallor, with a slight yellowish tinge, amounting to bronzing on the neck and forearms; conjunctivæ of normal color. The urine always contained a moderate amount of blood, even when drawn by catheter, to avoid a possible vaginal discharge. The average analysis was as follows: Acid, dark, 1020, trace of albumen, considerable sediment of mucus, bladder epithelium, and free blood, and although repeated examinations were made, no casts were found, except on one occasion, when a few hyaline ones were discovered. On August 8th, she complained of abdominal pain, and vomited three blood-clots, one as large as a two-ounce bottle. Nothing abnormal was found on abdominal examination, except slight tenderness in the epigastrium. On the 24th of August, she was sent to the Convalescent Home, at Waverley, feeling, at that time, fairly strong. For a week she did very well, but at the end of that time, she again vomited a small amount of blood, and was brought back to the hospital September 7th, in a very weak condition. At this time, the extreme pallor was the chief feature, lips and finger-nails being nearly white. Her urine still contained blood, but no casts, and it was noticed that her gums bled easily. She was put on a full diet, with plenty of milk and eggs, and given saccharated oxide of iron, gr. v, and arsenious acid, gr. 1-40, three times daily. She steadily improved in strength, and also in color, as was evident on ordinary examination, and was also shown by the blood counts given below. Her temperature ranged from 98° to 100.5° F., and her pulse averaged about 90. Her bowels moved two or three times daily, slightly loose. Part of the first count was made by Dr. F. B. Harrington, the second by Dr. Harrington and Mr. F. C. Woodbury; the others by the reporter, and are as follows:

Sept. 10th and 11th.	Average of	4	counts,	1,239,500	red corp. in 1. c. mm.
" 22d and 23d.	"	8	"	2,211,750	"	"
October 2d.	"	2	"	2,262,000	"	"
" 15th.	"	2	"	2,755,000	"	"

There was no increase in the number of white corpuscles.

The treatment with iron was begun September 10th, and the arsenic added September 12th, and the rapid improvement in the blood is noticeable. The fact that she was rapidly losing color before this treatment was begun, although she was under the best hygienic conditions, is certainly significant. The hæmorrhages from the stomach were slight, and insufficient to account for this loss of color, and the escape of blood in the urine and from the gums, continued during the improvement. She left the hospital October 17th.

In the two following cases, the diagnosis of pseudo-leucocythæmia was made, the first purely splenic, the second lymphatic, and in both cases, the improvement under treatment, as shown by the blood-count, is noticeable.

Case III. Alfred M., twenty-five years old, a tailor by trade, entered the hospital September 23d, 1885. A native of Canada, where he has lived all his life, with the exception of the last five years, which were spent in Worcester, Mass. Family history good. With the exception of "slow fever" fifteen years ago, and typhoid fever seven years ago, his general health has been good. Never had chills and fever. Habits unobjectionable. For the last three years, patient has had a cough, with bloody mucous expectoration, and, at times, slight hæmorrhages from gums, lips, and nose, these hæmorrhages occurring nearly every day for the last year. Has never noticed blood in urine, or fæces. Has been weak and short of breath, and able to do but little work for over two years. For the last two years, he has been jaundiced, his urine dark-colored, and his dejections of a grayish-white color, with a slight yellowish tinge. A year ago, his attention was called by a physician, to a swelling in the left side of his abdomen, which has been increasing slowly since. Slight swelling of legs for eight months. Bowels generally slightly loose, averaging three or four dejections daily. Has lost, in two years, about twenty-five pounds in weight. Is free from pain.

The patient is markedly jaundiced and very pale; fairly well nourished; slight œdema of feet and legs. A few bilateral moist râles detected in the lungs, but nothing else abnormal on thoracic examination. Abdomen distended on the left side, where a smooth, hard mass is found on palpation, extending from under the ribs nearly to the median line, and downward to within two inches of the crest of ilium. This area is flat on percussion. A distinct notch is to be felt on the inner edge of the tumor, just above the umbilicus. Deep inspiration causes a descent of the tumor over an inch. No modification in size of liver. The urine was dark-colored, acid, Sp. gr. 1015, bile present in large amount, slight sediment, no albumen.

The treatment consisted of a liberal diet, and acid arseniosi, gr. 1-40, and Pil. ferri carbonatis, gr. iij, three times daily.

The patient's temperature, pulse, and respiration remained normal, and no apparent change occurred in the size of the spleen. The jaundice diminished slightly, and he improved noticeably in strength and color. The daily slight hæmorrhages, spoken of in the history, continued.

The improvement in the blood, as shown by the hæmatometer, was as follows:

October 8th.	Average of 3 counts,	1,814,666	red corpuscles in	1	c. mm.
" 14th.	" 3 "	2,601,333	"	"	
" 25th.	" 2 "	3,982,000	"	"	

The proportion of white to red corpuscles was, at one count, found to be as one white to 348 red; at another time, one white to 770 red corpuscles — that is, within normal limits.

Patient was discharged November 14th.

Case IV. Wilhelmina H., forty-four years old, born in Sweden, married, entered the hospital October 14th, 1885. Family history good. Has previously been strong and well, and has had six children, one miscarriage, and one still-born child within a space of fifteen years, the last child being born four years ago. Catamenia since then have been regular. Three or four years ago, first noticed a small lump in the abdomen, near the navel, and several small ones in groins, axillæ, and especially in neck behind ear, all of which have been gradually increasing in size, the abdominal increase being most marked. During this time, has lost color, flesh, and strength, and has had palpitation and dyspnœa on exertion, most marked during the last year. Has had diffuse abdominal pain, not very severe, and inconstant; diarrhœa alternating with constipation for the last year, the dejections usually preceded and accompanied by pain, but followed by relief; at times, has noticed a slight amount of mucus and blood in the discharges. No hæmorrhages from other mucus membranes. Anorexia and a feeling of fulness after eating. No vomiting, headache, or jaundice. Slight swelling of feet for a few days.

On examination, the patient is found to be somewhat emaciated and pale. Numerous enlarged glands, from the size of a pea to a horse-chestnut, to be felt in the neck, both in front and behind the sterno-mastoid muscle, extending from the clavicle to the ear, where they form a noticeable tumor. Similar enlarged glands in axillæ; one or two near the nipples. Epitrochlear glands as large as the end of little finger. Numerous enlarged glands in both groins, extending down into Scarpa's triangles. None to be felt distinctly in popliteal spaces. Abdomen irregularly and considerably distended, chiefly in the umbilical region. On palpation, several large, firm masses, having a smooth surface, and slightly tender on pressure, are to be felt above and to the left of the umbilicus, and numerous smaller, less distinct masses elsewhere in the abdomen, but chiefly in the umbilical region. Skin freely movable over these bodies, which appear to be movable in the abdominal cavity. Slightly dull on percussion over the largest of these tumors, resonant elsewhere. No increase in hepatic area, and no enlargement of the spleen was detected. Heart normal. Feeble respiration, and a few moist râles at the base of both lungs. Urine normal. The blood-count on entrance, was — average of two counts — 1,649,000 red corpuscles in one c. mm., and the proportion of one white to 824 red corpuscles. She was put on a full diet, and given acid. arseniosi, gr. 1-40, and Pil. ferri carb., gr.iij, three times daily.

During her stay in the hospital, she had, at times, considerable abdominal pain and flatulent distension, due, it was thought, to the obstruction to the movement of the intestinal contents by the pressure of the abdominal tumors — enlarged mesenteric glands (?) — described above. Turpentine stupes, and especially enemata, followed by free dejections, gave relief to the patient. The temperature varied from normal to 100°, staying generally about 99° F. The pulse varied from 90 to 100, the respirations from 30 to 35. There was no apparent change in the size of the numerous tumors during her stay in the hospital, but her strength and color evidently improved. On November 1st, the blood count — average of two counts — was 2,505,000 red corpuscles in one c. mm., and the proportion of one white to 658 red. She was discharged November 26th.

In two other cases where the anæmia was very marked, and was due to definitely ascertained causes, namely, hæmorrhages, the blood was counted, and found to be as follows:

Case V. Catherine S., intestinal hæmorrhage for over eight months.

October 2d.	Average of 2 counts,	981,000	red corpuscles in	1	c. mm.
" 18th.	" 2 "	1,154,000	"	"	

Case VI. Hannah M., profuse uterine hæmorrhages for several years, dependent upon malignant disease. October 3d, one count, 1,478,000 red corpus-

cles in one c. mm. As a check experiment to test the accuracy of the instrument, the blood of a healthy man was also counted, and found to contain 4,680,000 red blood-corpuscles in one cubic millimeter.

TYPHOID FEVER IN SOMERVILLE, MASS.

BY THOS. M. DURELL, M.D., HARV.
City Physician.

DURING the latter part of August a case of typhoid fever occurred in a house just over the city line, in Medford. This house is located in a valley, the land around it which is used for farming purposes, and on which large quantities of night-soil has been used, slopes towards the house. The house is an old one with a damp, musty cellar, and a sort of shed in which is situated the well used for cooking and drinking purposes. The vault, or rather the hole in the ground used as a vault, is situated on a higher level than this shed, and is only twenty-four feet away from the well. This well is, practically, in the centre of this whole slope, and must, necessarily, catch all the filth from it.

The family living in this house at the time of the outbreak of the sickness, consisted of three persons, namely: father, mother and daughter; all of them took the disease, the mother's case proving fatal. The man who worked for this family, and who drank the water from this well, lived in one of four small houses located near this first one. These houses were close together and have one common vault. This man was sick some time before calling a doctor, and all of this time used the common vault.

There was another case in this house, one in the next, three in the third, and one in the fourth.

An analysis of the water from the well when the epidemic started (which was kindly made for me by Mr. Geo. H. Cowdin, of Somerville) showed large quantities of impurities and organic matter, some of these being in such large quantities as to be easily detected in the water as it came from the well without evaporation.

The main point of interest in this series of cases is their probable origin and method of transmission.

Therapeutical Memoranda.

WEIGHTED SHOES IN LOCOMOTOR ATAXIA.

A THERAPEUTICAL NOTE

BY ALLAN MCLANE HAMILTON, M.D., OF NEW YORK.

THOSE of us who are in the habit of seeing locomotor ataxia, especially in its second and third stages, have our sympathies taxed to their utmost, by the helplessness of the tabetic patient and his difficulty of getting about. There is very little to be done at best, and for this reason the case seems sadder than ever.

For such ataxics I have been in the habit during the past four or five years, of suggesting a simple mechanical device which has done so much good, that I think it worthy of publication. I allude to weighting the anterior part of the feet. Many ataxics whose locomotion was exceedingly difficult and distressing, have worn their weighted shoes constantly since I ordered them, and have led far happier and more comfortable lives.

Those at all familiar with the peculiar heel gait of the ataxic, knows that there is more or less weakness of the peroneus longus, and a failure to act against its opponent, the tibialis anticus, which is strongly contracted. Buzzard and Jackson first called attention to this explanation of the disorderly walk which largely depends upon what the former calls the "over-movement of the associated muscles." The use of properly adjusted toe weights serves two purposes — *first*, to overcome the tendency to violent hyper-flexion, *secondly*, to create an exaggeration of subjective consciousness of movement and location. The loss of plantar tactile sensibility is compensated by the perception of weight. In some cases with the adjusted weight it is possible for the patient to walk in the dark, which under other circumstances he could not do.

The weight, which should not be so great as to produce fatigue, may consist of a leaden insole, or of a plate fastened between the soles. A few experimental trials will enable the physician to determine just how much lead is needed, and where it should be placed. For those cases which last some time, the degree of comfort is sometimes very great, and the patient's gait is less apt to attract the attention it would otherwise, thus saving him much mortification and giving him greater confidence.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

JANUARY 11th, 1886, DR. G. H. LYMAN in the chair.

DR. S. L. ABBOT read a paper on

PERICARDITIS TREATED WITH SALICYLATE OF SODIUM.[1]

DR. FRANCIS MINOT said that salicylic acid and its compounds have so extraordinary an effect in cases of acute rheumatism, that it is reasonable to suppose that they might modify the character and duration of pericarditis. The natural history of the disease, however, shows so variable a duration, that, in order to judge of the effect of a remedy, we must examine a large number of cases in which it has been used.

Da Costa has grounds for the opinion that pericarditis is not influenced by internal medicines. The speaker had had no personal experience in the use of salicylates in the treatment of this affection, but he had been disappointed with the effect of internal remedies in general, when given for its control. He is rather inclined to think that it is a self-limited disease, and, that unless the patient is broken down by rheumatism or otherwise, that the prognosis is good. He is inclined to treat it with external irritants, such as mustard or iodine, but not with blisters.

DR. JAMES AYER agreed with the last speaker, that, in order to form conclusions, we need to judge from a very large number of cases. Much can, of course, be done for temporary relief with morphia and digitalis.

DR. ROTCH remarked that it would be difficult to ascribe, in the third case, the disappearance of the friction sound during the administration of the salicylate of sodium, and its return on the drug being omitted, to the influence of the salicylate; as with the large amount of fluid represented by the readers' percussion in

[1] See page 49 of this number of the Journal.

this case, a slight increase in the quantity of fluid might cause the friction sound to disappear, and an absorption of the same quantity allow it to be heard again.

DR. LYMAN said that pericardial effusion has been looked upon with great dread, on account of its possible results, both present and future. He has, however, been led to change his opinion upon this point; for, while cases are not unusual, and while he has himself seen many recoveries, he has met with no death. He has not made use of any specific treatment.

He asked the Society if any difference has been observed in the effect of salicylates, dependent upon the form of rheumatism in which they had been used. With acute cases having large effusions into the joints, the effect, as is well known, is commonly marked. He had recently had a number of cases of acute fibrous rheumatism, in which there was pain, with heat, redness, and stiffness of the joints, and a dry tongue, but with no effusion; and in these cases, no benefit had been had from the drug. One of them had developed typhoid fever before recovery. The speaker was interested in knowing if any similar distinction had been noticed by others.

DR. ABBOT, in reply to what had been said in the course of the discussion, remarked that at no time had there been effusion enough in either of the cases reported, at least in those that had been continuously under his own observation, to conceal the sounds of the heart. This met the suggestion, that in the course of pericarditis, it might be possible to be deceived by the disappearance of the friction, when it was only muffled by the fluid in the pericardium, and would be likely to reappear when that was absorbed. In the first case, the signs of effusion disappeared with the friction sound. In the second, there was no evidence of effusion at any time. In the third, there was an increase of the cardiac dullness, but the sounds of the heart were not obscured, whatever may have been its cause. In the fourth, by the report of the physician in attendance, the sounds of the heart were perfectly distinct when the friction disappeared.

AN UNCOMMONLY LARGE FATTY TUMOR.

DR. C. B. PORTER said that he had to present to the Society to-night, a tumor, which is exceptional in many respects. It is from a woman forty-seven years of age, and she has carried it for thirty-five years, it having begun to grow at the age of twelve.

Secondly, its size is exceptional. It weighs ten and a half pounds, drained of its blood and of a large amount of serum, and the patient was kept in bed for a week before the operation, in order to reduce the congestion and œdema, both of which were much increased by the upright position.

Thirdly, in its gross appearance, it seems to be a fibromatous lipoma, although no microscopic examination has yet been made.

Fourthly, Bilroth states that fatty tumors are "very rare in children." This began at the age of twelve.

It hung pendulous from the middle of the outer surface of the right thigh, and it was surprising how little it impeded locomotion. Her carriage was such that no one would have mistrusted that she had such a growth, it being perfectly concealed under her skirts.

POISONING BY NUTMEG.

DR. LYMAN said that he had recently seen a woman in a state of hysterical delirium, more or less unconscious of what was going on, and from whom it was impossible to get any history. She was in this condition when discovered by her friends. She had a good pulse. On the following day, when she had recovered, she stated that she had eaten a nutmeg for its supposed effect on menorrhagia, and the speaker learns that there is an impression in the community that nutmeg is of value in that affection. Her symptoms were those that are stated in books to be caused by large doses of nutmeg. There was no effect upon the trouble for the relief of which it had been taken.

DR. BUCKINGHAM said that he had reported a case of nutmeg-poisoning six years ago. His patient had taken two nutmegs, and complained of numbness, a feeling as of swelling of the head, an uneasy sensation at the heart, and drowsiness. Dr. Swift had had, he believed, a case at about the same time.

OBSTETRICAL SOCIETY OF BOSTON.

THE Twenty-fifth Anniversary of the Obstetrical Society of Boston was celebrated by a dinner at Young's Hotel on the evening of January 5th, which was the exact date of the organization of the Society. The Society met at half past six o'clock, and sat down to dinner at seven. All the members were present with the exception of four, who were unavoidably prevented from attending. The President, Dr. A. D. Sinclair, presided, having on his right and left the invited guests, Drs. Fordyce Barker, of New York, Gilman Kimball, of Lowell, and John Homans, of Boston. The post-prandial exercises were opened by the following address by the President, Dr. Sinclair:

GENTLEMEN: — We have met together this evening to celebrate the Twenty-fifth Anniversary of the Obstetrical Society of Boston. It is indeed appropriate that we should make this day memorable, for two reasons: first, because our Society is the earliest organization of its kind in the country; and secondly, because the social element has always been an agreeable feature of its meetings.

Let me then cordially greet you, each and all, assembled on this festive occasion, and especially our distinguished guests, who honor us this evening with their presence.

Our Society was organized during that period of great agitation which preceded the outbreak of our Civil War, and its childhood was more or less disturbed in consequence, like all things else, local and national. The infant Society, therefore, although of healthy parentage, was not robust in its earliest years. In its second and third years especially, signs of feebleness were so apparent as to alarm its promotors, who resolved that an effort be made to strengthen their precious offspring. Its nutrition and surroundings were discussed by the doctors, and change of scene, with cheerful social intercourse were suggested by one of the maturest among them. So earnest, indeed, was this last adviser, (Dr. Benjamin E. Cotting), that he offered to take the starveling under his own roof for a time, in order that a trial be made of the regimen he proposed. The treatment was successful. Others followed in due order, who adopted the same plan, and it soon became apparent that all signs of mental and physical weakness had disappeared from the once feeble body. Our meetings from that time

have been held monthly at the houses of members, during nine months in the year. The scientific and social elements have blended at our meetings. Harmony and good fellowship have ever prevailed, and to be elected a member of the Society marks an era in the history of the candidates.

Of the sixteen (16) original members, the names of five (5) are now on the roll of the Society, namely: Drs. B. E. Cotting, George H. Lyman, John P. Reynolds, Charles D. Homans, and A. D. Sinclair. Seven (7) have died, namely: Drs. Walter E. Channing, John Homans, Charles G. Putnam, Anson Hooker, Charles E. Buckingham, Calvin G. Page, and Lucius M. Sargent. Four resigned.

The Constitution of the Society limits the number of its active members to thirty, who must also be members of the Massachusetts Medical Society.

I might narrate on this occasion much that is interesting in the early annals of our Society, but in so doing, I should only rehearse what has become already familiar to you in Dr. Cotting's history of the first one-and-twenty years of its existence.

I have already indicated that ours is the parent society of its name in the United States. Its inauguration day is not far behind that of the Obstetrical Societies of Berlin and of London. The former celebrated its twenty-fifth anniversary but a few months ago, the latter in February, 1884. By a singular coincidence, the first public meeting of the London Society was held on the same day of the month as ours, namely, the 5th of January, Anno, 1859.

The papers read from year to year, with the discussions which followed, and the numerous less formal communications made, have been worthy of our Society. Never has there been any desire apparent to magnify the individual at the expense of the subject treated; to ascertain the truth of the matter in hand has always appeared to be the salient motive in the work of our organization. Indeed, in a society so limited as ours, one in which the members are personally so intimately known to each other, other than honest efforts could find no recognition.

In a more formal address, I might be expected to review in a measure, the work done by this Society in the past five-and-twenty years. Fortunately for me, I do not feel called on to do that now. I will say, however, that little of what has been done at home or abroad to advance our specialties, has escaped observation, and a stone may have been added to the cairn of science within our own borders. Since the birthday of this Society, the science and art of midwifery has been remodelled and improved. Convulsions, placenta prævia, accidental hæmorrhage, and puerperal septicæmia have lost their terror on the one hand, as has abdominal surgery on the other. The department of diseases of women has adopted a new name, and become almost a new creation. We have, as a nation, good reason to congratulate ourselves that much of that which constitutes this advance has originated within our own country. Yet we can never forget to honor the great pioneers in obstetrics and gynæcology at home and abroad, who, by their genius and labors, have made future research easier for their successors.

It would be proper for me, as I have spoken the names of my early associates who have gone over to the majority, to pay a tribute to their memory on this occasion. This duty I have asked another, better qualified than myself, to perform, who will tell us of men, distinguished in their day and generation, who died beloved and regretted.

The grave has but just closed over all that was mortal of *him* who was *last* admitted a member of this Society. His untimely end has cast a shadow over us. Learned, manly, and amiable, he won the heads and hearts of his associates. In Dr. Frederick Howard Lombard the Society has lost a valuable and promising member, whose memory will not early die.

"Lange leben ist nicht viel leben,
Viel wirken ist viel leben."

We regret that distance, the season of the year, or physical infirmity have prevented many distinguished men, at home and abroad, from being present, the only alleviation for which lies in the spirit of their replies, which will be read to you in the course of the evening.

In concluding these introductory remarks, let me take this opportunity to express my thanks to our Committee of Arrangements, the result of whose labor speaks for itself in this sumptuous entertainment. Furthermore, let me here acknowledge the ready aid afforded me by associates on this eventful occasion in the history of the Obstetrical Society of Boston.

The history of the Society was then sketched by DR. B. E. COTTING, an honorary member, who was one of the founders and who had not long since published an account of its origin and growth.

DR. GEORGE H. LYMAN was called upon to speak to the memory of the deceased original members, and responded as follows: —

MR. CHAIRMAN: — You ask me to say something of the older of the original members of our Society; but though it was my privilege to be associated more or less with all of them, and though they were all men of marked individual peculiarities, I have really nothing to say which has not already been said.

Drs. Channing, Homans, Hooker, Putnam, Buckingham, and others, to whose fidelity we owe it that the Society did not abort in its formative period, were all of them men of large experience and wise foresight, and on such an occasion as this, it would be ungrateful in us not to recall their memory, if nothing more.

Dr. Channing, the oldest of them, the first Professor of Obstetrics at the Harvard School, and the first President of this Society, would have been one hundred years old had he lived to be with us this evening! Imagine if you can for a moment the changes in pelvic pathology, and in our knowledge of the diseases of the uterus, ovaries, etc., since he began to teach obstetrics and gynæcology at twenty-nine years of age. Think of the incredulity which the men of those days would have shown had any one prophesied the then almost immediate future of ovariotomy, hysterectomy and pelvic surgery generally! Ovariotomy was bitterly denounced by some of the best of them as unjustifiable. A reported and apparently well authenticated and successful case of removal of uterus and ovaries was unhesitatingly pronounced *a lie*, the speculum was quite generally considered as a vicious, immoral thing. Dr. Channing, I think, would have been the least incredulous of any of them, for he was always in the forefront of progress, and, being an enthusiast himself, was naturally disposed to contemplate future possibilities with an optimistic vision. He lived to witness the days of ether, and no one could have a better appreciation of the enormous value of such a discovery. His reputation for having wit and quaint diction are familiar no doubt to most of you.

Then came Dr. Homans, with his large practical experience, and that gentle courtesy that made him beloved of all men. I can never forget his pleasant recognition of myself, and his kindly advice as to deportment and personal habits, especially smoking, and though I soon discovered that he himself indulged in tobacco, a fact which took a little from the weight of his advice, it detracted nothing from the benevolence of his motive. He left such loving memories behind among his patients and friends as few others have, and a professional reputation which I am sure we all of us are here glad to recognize as being so worthily perpetuated by his immediate descendants.

Dr. Hooker was another marked character in the professional arena of those days, not so familiarly known, perhaps, in Boston, as his field was in another town, but he was a constant attendant upon our Societies, and those of you who were members of the Massachusetts Medical Society will remember well the deference which was always paid to his opinion on any question of obstetrics, and very naturally, too, for it was discovered later that his midwifery cases numbered nearly if not quite 10,000 — a very rare experience — the deductions from which by an intelligent observer could not have been otherwise than valuable.

Next we have a more recent memory, Dr. Putnam, with his operative skill and his helpful hand to every brother in trouble. Up to his day the use of the forceps was considered almost in the light of a capital operation, a dread alternative for dire emergencies only, and above all things requiring a previous consultation! Two, possibly three pairs were considered quite sufficient for Suffolk County, and any young man adventurous enough to own them was quite likely to be advised to leave them at home for fear of temptation. Dr. Putnam, so far as I know, was the first here to encourage their freer use, and no doubt some here present have a grateful remembrance of his unobtrusive but instructive assistance.

Of Dr. Buckingham, with his caustic pen and positive opinion, if sometimes too aggressive, always instructive, and never wilfully unjust, I need hardly speak, for he was even more of our own time. To appreciate his sterling merits, it was necessary to know him well, and be well known of him. His circumstances made every patient important to him, but never so much so as to tempt to mean or underhand ways, for I believe he was the soul of professional honor. He was one with whom a friend could in an emergency leave his patients with entire confidence. Such being the case, what wonder that any dereliction on the part of others should call forth his keen and cutting sarcasm, vigorously felt and vigorously expressed. He was taken just as the modern field of practice was coming into full view, and he in the full prime of his powers and usefulness.

In the days of the older of the men of whom I have spoken, the word gynæcology was almost unknown. In fact, I well remember a discussion among a small number of the staff in the hospital consulting-room as to its pronunciation, derivation, etc., when a journal bearing that title was produced as a curiosity. What would they have thought of some of the absurd affected nomenclature which has become current since; of Kolpo-Kleisis, Hystero-Kleisis, Hystero-Cysto-Kleisis, Kolpo-Stenotomy, Kolpo-Ecpetasis, Cysto-Ecpetasis, Cysto-Stenosis, Hystero-Ephelkosis-Anakainosis, and all the *-raphy's*, Trachelo, Perineo, etc. How they would have been sent incontinently to their dictionaries! But though many of these terms, and the procedures indicated by them, had not yet risen above the medical horizon, I have as yet seen no statistics proving that the mothers and wives, and especially the young women were very much the losers. I say this with some hesitation for fear of misconstruction, for I am a firm believer in a wise gynæcology, otherwise I should belie a large part of my own professional life. I have practiced it according to my lights for forty years, and under discouragements from my elders which are now happily unknown, but I am bound to confess my belief that many things are done in these days, and especially in the operative way, that had better be left undone. A distinguished hysterectomist in Edinboro, recently told me that he had come to the belief that the operation as now advocated was unjustifiable; that he considered the present mortality as much too high, in view of the fact that the mortality in cases not meddled with was still less, and that he should hereafter confine himself to those rare cases only in which a fatal result if let alone seemed inevitable.

We all know the story of laceration of the cervix, of colporaphy, of discission of the cervix, of electrolysis; we have all heard, on one hand, that the perineal body is after all a myth, and on the other, that the ovaries are of little or no account as a factor in many of the cases, in which a very few years ago they were supposed to be the chief source of trouble.

Probably all these operative procedures and many more which are to follow, were and will be necessary to the proper evolution of the subject, feelers as reaching in various directions to discover the right path, but I also believe that much of this sort of experimentation should be confined to stricter limits and to the hands of those of you who by experience and practical knowledge will be able to evolve from them solid foundations for your successors.

THE FUTURE OF THE SOCIETY

formed the subject of the remarks of DR. ALFRED HOSMER, who was followed by DR. JOHN P. REYNOLDS, who eloquently alluded to the past influences which had so largely contributed to the formation of such a Society, and humorously sketched the possible future of American obstetrics. DR. FORDYCE BARKER responded for the guests of the evening, and DR. JOHN HOMANS replied in behalf of gynæcology. The closing speech of the evening was made by DR. GILMAN KIMBALL, who gave an account of his early ovariotomies.

Letters of regret at their enforced absences were read from Drs. Emmet, Thomas, Lusk, of New York; Skene, of Brooklyn; Goodell, of Philadelphia; H. P. C. Wilson, of Baltimore; J. Taber Johnson, of Washington; D. H. Storer, of Boston; W. S. Playfair, of London; A. R. Simpson, of Edinburgh; G. H. Kidd, of Dublin; T. Lasavewitch, of Kharkoff, and Professor Litzmann, of Berlin. The Society then adjourned, having voted to celebrate the fiftieth anniversary by a similar festive occasion.

— The *Medical Times and Gazette*, one of the four medical weeklies published in London, and one of the most readable of our exchanges, has, we regret to learn, suspended publication.

Recent Literature.

An Atlas of Clinical Microscopy. By ALEXANDER PEYER, M.D. Translated and edited by ALFRED C. GIRARD, M.D., Assistant Surgeon United States Army. First American, from the manuscript of the Second German edition, with additions. Ninety plates, with one hundred and five illustrations. New York: D. Appleton & Co. 1885.

Dr. Peyer's "Atlas" contains eighty-nine plates, illustrating the microscopy of the blood, mammary secretion, secretion of the female sexual organs, urine, sputum, contents of stomach, intestines, and abdominal tumors; and an additional plate, copied from Friedländer, illustrating certain micro-organisms. All the plates, with the exception of the one mentioned, and one other on the examination of blood, are original drawings. Most of the plates are very good; there are some exceptions, however, which detract from the value of the book. Among these, the figures of hyaline and of fibrinous casts may be mentioned as not accurately representing these bodies. The same is true of some of the figures representing the epithelium of the urinary tract. The sediment of the urine in acute parenchymatous nephritis, is not represented satisfactorily. The author has made too much of spermatorrhœa, we think; ten plates (one-ninth of the whole number), illustrate this condition. The text is inferior to the plates, and several of the author's statements are not reliable. A good work on clinical microscopy would supply a real want; we cannot, however, recommend this one as wholly satisfactory.

The translation is, on the whole, well done, though it lacks smoothness in some parts, and one is conscious, when reading the text, that it is a translation. The publisher's part of the work, it is, perhaps, needless to say, is above criticism. The plates are well executed, and the book is well printed on good paper. In these respects, the volume is a very attractive one.

Practical Suggestions Respecting the Varieties of Electric Currents, and the Uses of Electricity in Medicine, etc., etc.. By AMBROSE L. RANNEY, M.D., Professor of the Anatomy of the Nervous System in the New York Post-Graduate Medical School and Hospital, etc., etc. New York: D. Appleton & Co.

This very long title covers a small book of about one hundred and fifty pages, which gives a pretty fair *résumé* of what has been written recently about the practical methods of applying electricity in medicine. It would have given sufficient information if the references to the makers of instruments had been omitted from the text, as well as from the illustrations, and, in our opinion, would have been in better taste.

A Guide to the Practical Examination of Urine. For the Use of Physicians and Students. By JAMES TYSON, M.D. Fifth edition. Revised and corrected. With colored plates and wood engravings. Philadelphia: P. Blakiston, Son & Co. 1885.

The rapidity with which successive editions of this manual are exhausted, proves that it supplies a demand. The present edition has been carefully revised and somewhat enlarged. The new tests for albumen, which have been suggested during the past few years, have been introduced; also additional tests for sugar — namely, the picric acid and potash test, and the indigo-carmine test. Place has also been given to the determination of sugar by polarimetry, and to the consideration of mucin, peptone, inosite, levulose, lactose, and acetone and acetone-producing substances. We have had the pleasure of recommending the earlier editions of this book, and it is sufficient to repeat the opinion we have so frequently expressed, that it is an excellent book; the best of its kind in the English language. It should be owned by every practitioner and student of medicine.

An Introduction to the Study of the Compounds of Carbon; or Organic Chemistry. By IRA REMSEN, Professor of Chemistry in the Johns Hopkins University. Boston: Ginn, Heath & Co. 1885.

We recommend the book as one well adapted to the needs of those who are beginning the study of organic chemistry. The number of compounds treated of is smaller than is usual in works on organic chemistry; the compounds selected being such as best serve to make clear the fundamental principles of the science. The author has endeavored throughout to present the subject in such a manner as will lead the student to see for himself the reasons for adopting the prevalent views in regard to the structure of the carbon compounds. More than eighty carefully-selected experiments, such as may be performed in any chemical laboratory, are described, illustrating the methods used in preparing the principal classes of compounds, and the fundamental reactions involved in their transformations. This is a feature of the book which specially meets with our approval, believing, as we do, that experimental work of this kind is necessary, if the student is to get a clear idea regarding organic compounds and their changes.

Brain Rest: being a Disquisition on the Curative Properties of Prolonged Sleep. By J. LEONARD CORNING, M.D., Formerly Resident Assistant-Physician to the Hudson River State Hospital for the Insane, etc. Second edition. New York and London: G. P. Putnam's Sons; Knickerbocker Press. 1885.

This edition is revised and enlarged, with additional illustrations. The book is written in an interesting style, and although it will, perhaps, attract the lay reader rather than the physician, the latter will find considerable practical information on the systematic treatment of insomnia, besides much on the circulation of the brain, and the physiology of exhaustion and repair. The author's instruments for carotid compression and simultaneous application of electricity, are described at some length, and their uses explained. Whether this invention, which is intended to lessen the cerebral circulation, will prove as valuable in the hands of the profession at large, as in those of its projector, is a question of the future. The book contains one hundred and thirty-five pages, and is of a convenient size for the pocket.

Acne, its Etiology, Pathology and Treatment. By L. DUNCAN BUCKLEY, A.M., M.D. New York and London: G. P. Putnam's Sons. pp. 280. 1885.

This book is a comprehensive, painstaking and trustworthy treatise, not only upon what is commonly known as acne, but upon the diseases of the sebaceous glands in general, and is worth the attention of any one interested in the subject. G. H. T.

Medical and Surgical Journal.

THURSDAY, JANUARY 21, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

LAPAROTOMY IN PENETRATING STAB AND SHOT WOUNDS OF THE ABDOMEN.

THE rapid progress of surgery in the past two decades has presented to the mind of the surgeon a series of more or less difficult problems in regard to the advisability of novel operations or methods of procedure, which are earnestly recommended by some surgeons and perhaps as decidedly condemned by others.

One of the most interesting of these problems, the question of laparotomy in wounds of the abdomen, is, however, by no means a modern operation as Heister, in his work on Surgery published in 1739, speaks favorably of it, even quoting a successful case, and the various authors of the brilliant era of military surgery at the beginning of this century, discuss the subject fully.

Of late years some enthusiastic spirits have claimed for the operation as great a future and as recognized a position as that of ovariotomy; but at a recent discussion on the subject by the Surgical Section of the New York Academy of Medicine, a much more conservative opinion was expressed. The various sources of danger, arising from unfavorable surroundings of the patient and the lack of a thorough knowledge, by the surgeon, of the details of the operation, were fully recognized, and it was well said that laparotomy for wounds of the abdomen "is not to be attempted, even in so-called favorable cases, unless the operator could avail himself of many of the recognized means of procedure necessary to control the shock of the operation and were sufficiently familiar with its steps to accomplish the work with accuracy and despatch."

A discrimination was made in favor of stab wounds, which, as a rule, are not associated with such dangerous symptoms as shot wounds. In the latter no particular attention need be paid to the character and calibre of the weapon, as Parkes' series of experiments on dogs[1] prove that no exact relation exist between the extent of the injury and the size of the missile. In regard to the position of the wound, it should be said that Hamilton's observations seem to show that wounds in the inguinal regions have a remarkable immunity from serious results.

The important practical elements in the consideration of these cases are shock, hæmorrhage, and escape of fæces, and the main difficulty lies in properly estimating, in a given case, to what extent hæmorrhage is a factor in the production of the shock. Although a varying amount of shock may be caused by the blow of the bullet or weapon, especially if the wound is near the epigastrium, the statement can still be safely made, that in most cases, if the shock is considerable, hæmorrhage is taking place. The anatomical relations of the omentalic and mesenteric vessels are such as to cause them to bleed very rapidly after injury, to which they are especially exposed, so that a wound of a small vessel may give rise in a short time to a considerable and even to a dangerous hæmorrhage. Hence laparotomy, if done at all, it is to be done at once, or as soon as the necessary arangements can be perfected. The presence of meteorism is, of course, an indication of injury to the abdominal viscera, but it should be borne in mind that visual proof of perforation is required, even the protrusion of the gut through the external wound not being conclusive on this point. Perforation also is not invariably fatal, as several cases of gun-shot wounds of the abdomen with recovery, accompanied by the passage of the bullet per rectum in from three to forty days, are reported in the surgical history of the War of the Rebellion. The actual escape of fæces, however, is an occurrence most to be dreaded by the surgeon, and, in common with any other like symptom, such as a gush of urine, indicating with certainty a laceration of the abdominal viscera, is the strongest inducement to laparotomy which in such a case most probably offers the only chance for recovery.

The probable occurrence of hæmorrhage, as indicated by an excessive amount of shock is also a strong incentive to active surgical interference, and is thought by many to justify an exploratory incision which allows the entrance of air into the abdominal cavity and thus momentarily checks the hæmorrhage. If, then, actual laparotomy is done the difficulties of the operation are much increased by the fact that the surgeon is not concerned with an abdominal cavity whose walls have been rendered flaccid and more or less atrophied by the long-continued pressure of a tumor, or where the bleeding area is circumscribed by the nature of the case; but that he has to seek for a bleeding point in a so-called cavity all of whose contents lie throughout in very close contact with each other, and where even the normal relation of the various organs may be disturbed and clouded by coagula, all of which may have to be carefully removed before the lacerated vessel is found. Hence it has been justly remarked that "the intestines and omentum should be thoroughly examined by a preconceived method rather than by the rough handling associated with illogical haste." In fact the true answer to the question of danger in these cases will be found to lie in the *amount of hand-*

[1] Journal of American Medical Association, 1885.

ling of the viscera required in order to check the hæmorrhage, remove coagula or fæces, place intestinal sutures if necessary, and perform the toilette of the peritoneum.

It is, however, in the doubtful cases, where there is no proof of laceration of the viscera and the evidence of hæmorrhage is slight, that conservative surgery holds up a warning finger to the ambitious operator and, reminding him that the patient may recover under expectant treatment, points out the many difficulties and dangers of the operation as it is at present understood. Whatever new facts the future may bring to light it cannot be expected that laparotomy for penetrating wounds of the abdomen will ever become a routine procedure, but it may be confidently hoped that its position will be a high one amongst those operations which are only to be attempted, with strict observance of cleanliness, by a surgeon possessing some experience of the parts affected.

THE PLEA OF INSANITY AND EXPERT TESTIMONY IN THE GOODWIN CASE.

LAST August (27th), Mr. Goodwin, of Lawrence, Massachusetts, went into the office of Mr. Swan, and after a quiet talk shot him dead through the back of the head. There had been no altercation or violent talk overheard, and the two men were within easy sight and hearing of a clerk. Goodwin at once telephoned to the police to arrest him, and, upon their not coming, went to the station and gave himself up. He was in great need of money and claimed that he had been overreached and defrauded by Swan, as was probably true, in regard to some investment of his and in business transactions arising out of them. He acknowledged that he had gone to Swan's office with the intention of shooting him in case he did not get satisfaction for his wrongs, which were real, in part at least and perhaps altogether. So far Goodwin acted with all the method of the sane man, and there was, as he said, reason for extreme anger on his part at his treatment by Swan. He was an ill-balanced man, intensely devoted to one idea at a time and with fixed ideas so strong as in some cases to suggest the doubt whether they were wholly the false beliefs of a sane man, if not entirely the morbid delusions of an unsound mind. He was apparently quite honest in his statement, for instance, that the jury would bring in a verdict, in his case, of justifiable homicide.

Goodwin's father was preacher, poet, painter and farmer, eccentric, with a quick, violent temper, and subject to periods of mental depression. He died in Libby prison. His son showed similar qualities in early boyhood. A great-uncle's insanity was perhaps an exaggeration of the family tendency, perhaps accidental. Goodwin had been a prisoner at Andersonville during the war of the rebellion and came away emaciated, dull, stupid, and almost in a condition of mild, simple dementia from the starving, exposure and various horrors of that place. One friendly witness testified that the particular murder was a surprise to him, although he had seen Goodwin in a state of mind when he might have killed some one else.

Mr. Goodwin was shown to be clearly not of a thoroughly sound and normal mind. Indeed, no reasonable person familiar with his history, would think of maintaining that he could control his actions to the same extent as may be fairly expected of mankind in general, and yet few men well acquainted with mental disease, would testify that he was insane in the sense of being fully irresponsible for the deliberate and premeditated murder, even of a man who had grossly wronged him. It was the old question that came up with such force in the trial of Guiteau, when passion and party feeling were too strong for it to be fairly answered, at what point medical insanity or unsoundness of mind becomes legal insanity, or irresponsibility for crime; and there are some indications for the belief that Goodwin may have had, in a mild degree, the same form of insanity which, in Guiteau, was pronounced, primary insanity (*primäre Verrücktheit*).

In strict law, Goodwin should have been either hanged for murder, or acquitted on the ground of insanity. But, although the law does not recognize a limited responsibility, the court or the jury often does, and in this case, the judges evidently meant to make a verdict of murder in the second degree possible to the jury, in that they dwelt particularly upon the fact that the law does not define the amount of premeditation necessary to constitute murder in the first degree. The sympathy of the jury was naturally in favor of a man of narrowed limitations of self-control when exasperated to the last degree.

A distinguished surgeon of New York was called, as an expert, by General Butler, senior counsel for the defence, to answer the hypothetical question, which implied the insanity of Goodwin; but several physicians giving evidence for the government, without special training and experience in mental disease, upon protest from General Butler, were not allowed by the court to testify as experts — a step in advance, for which Judge Allen and Judge Gardner deserve the thanks of the medical profession and the community.

The verdict of murder in the second degree is, probably, quite satisfactory to the public, and to the scientific students of insanity, and we congratulate the attorney-general, as we have had occasion to do before, upon having prevented the plea of insanity from being used as a cloak for crime. Those politicians who think General Butler to be in his dotage, or breaking up mentally, evidently did not attend this trial, and have not conversed with the medical witnesses cross-questioned by him.

THE CODEX COMMISSION'S REPORT ON PEPSIN.

PROBABLY no medicinal agent is more extensively prescribed than pepsin, and there is, perhaps, none concerning whose real efficacy more doubt exists in the professional mind. The indications for its admin-

istration are not clearly established, nor is it certain that this substance, even with the addition of a dilute mineral acid, has precisely the same action in the human stomach on the ingredients of a meal as it has out of the body on albumen in a test tube. However this may be, there is a real interest in knowing the best means for determining the purity of this now standard medicament, for inert preparations abound.

It has been shown that it is not enough that the sample which is the subject of experiment shall dissolve a certain quantity of coagulated white of egg; this result may be obtained with pepsins of feeble digestive power, and simple solution is not peptonization.

Dr. Pierre Vigier, of Paris, appointed recently member of the Codex Commission to revise the pharmaceutical methods in use for the assay of pepsin, has published the results of a long series of experimental researches. He gives the following formulæ, which has been adopted by the Codex. A pepsin which will respond to this test is regarded as of good quality.

FORMULA A.

Take of Medicinal Pepsin in powder	0.50
Or Pepsin Extractive	0.20
Distilled Water	60.00
Hydrochloric Acid	0.60
Fibrin of sheep, calf, hog, washed and dried in the air	10.00

This mixture is subjected, in a wide-mouthed flask, to a temperature of 122° F. for six hours. At the end of this time, the filtered liquid ought not to show a precipitate, or become cloudy by the addition of a few drops of pure nitric acid, which is an indication that all the fibrin has been peptonized.

Vigier finds that the greater part of the pepsins of commerce have a digestive power greatly inferior to that required by the above standard. They may, indeed, dissolve fibrin in quantity very greatly in excess of their weight, but a copious precipitate will follow the addition of the nitric acid, which shows that the fibrin has not been peptonized, and, as is well known, the albumen is not assimilable except under the form of peptones. The only reagent which enables one to estimate the peptonizing power of a pepsin is nitric acid, introduced drop by drop; and, after numerous trials, Vigier has ascertained that it is best to employ for this test a fixed quantity of ten grammes of filtered liquid to which is slowly added, *guttatim*, nitric acid up to forty drops; above that quantity, the acid redissolves the precipitate formed.

The same experiments have shown that although the temperature of 122° F. (50° C.) is higher than that of the stomach, yet the maintenance of this temperature is necessary for a perfect result.

The Commission of the new Codex has, in accordance with these experiments, adopted the following criteria: "Pepsin in powder, or medicinal pepsin, obtained from pepsin extractive by the admixture of a certain quantity of dextrine, or starch, ought, in a quantity not exceeding fifty centigrams, to peptonize ten grammes of fibrin.

"The pepsin extractive (officinal pepsin of the Codex of 1866), which is found in commerce under the form of a brown extract, ought, in the dose of twenty centigrams, to peptonize ten grammes of fibrin."

The report of Vigier adds that these figures are not exaggerated; there are pepsins in the market, and among them that of Boudault, whose digestive power is twice as great as that indicated above. The fibrin employed is obtained by whipping the blood of a sheep, a hog, or a calf; that obtained from the blood of the ox is found, practically, not so good for the purpose.

Pepsin acts only in an acid medicine; the hydrochloric acid, which is the acid of the gastric juice, is that to which the preference should be given. The quantities of acid and water given in the above formula have been fixed upon after numerous tentatives, as those certain to give the best results.

An interesting experiment is given illustrative of the power of a limited quantity of pepsin to peptonize an indefinite quantity of fibrin, provided new supplies of acid are added at the same time. A complete artificial digestion having been obtained, in accordance with the conditions of the above formula, to the contents of the flask, still unmolested, a fresh quantity of fibrin was added, with a proportion of acidulated water equal to that already employed; at the end of six hours the digestion was perfect. This operation was repeated three or four times with the same result, only after the fourth digestion, the filtered liquid become slightly cloudy on the addition of a few drops of nitric acid. This experiment shows that the encumbering action of the peptones in artificial digestions diminishes in proportion as they are further diluted, and that the digestive power of the pepsin is augmented in the same ratio. It also shows that pepsin acts after the manner of living ferments; "from this," says M. Vigier, "we obtain a hint as to the beneficial effects of drinking freely during meals."[1]

The formulæ for the Wine and Elixir of Pepsin adopted by the Commission of the New Codex are as follows:

WINE OF PEPSIN.

Medicinal Pepsin	5 parts.
Muscadel Wine	100 "

ELIXIR OF PEPSIN.

Medicinal Pepsin in Powder	1 part.
Alcohol at 80	3 parts.
Syrup	8 "
Distilled Water	9 "
Flavor *ad libitum*.	

Twenty grammes of the Elixir or Wine of pepsin are equivalent to one gramme of pepsin in powder, and this quantity is necessary to digest ten grammes of fibrin.

As the strong alcohols precipitate pepsin from its solutions, it is only in a very dilute state that they can be used in conjunction with this medicinal agent; hence, for the preservation of pepsin, menstrua are chosen, as in the formulæ above given, which contains only ten to fifteen per cent. of alcohol. The amylaceous pepsins (like Boudault's), give better preparations with dilute alcohol than the saccharated pepsins.

The glycerites of pepsin, according to the Codex Commission, have little activity, and it is the same

[1] Bulletin gén. de thér., Nov. 30th, 1885.

with respect to other preparations which contain associated with pepsin, other ferments, such as pancreatine, or pharmaceutical products, such at hydrochloric acid, coca, quinine, bismuth, iron, etc.

The Commission, in concluding, emphasize the importance of the physician or pharmacist testing every preparation of pepsin of which he is the prescriber or vendor, in order that he may know the quality thereof, and if it be a faulty article, avoid its use or delivery. For such purpose, the very best criterion is the formula A, above given.

MEDICAL NOTES.

— Mlle. Tarne, Doctor of the Paris University, has been appointed honorary physician to the Queen of Italy. This lady passed, four years ago, brilliant examinations. There are now three women who are house students in the Paris hospitals.

— Leopold von Ranke, now more than ninety years of age, presents the anomaly of a man who has never taken any physical exercise, and is yet in perfect health. The great German historian has almost lived in his library, working for fifteen hours a day, and he has laid out more work which he hopes to complete before his one hundredth birthday.

— Lieut. Greeley has recently returned to Washington. His health is greatly improved, and he is now quite robust, although still suffering somewhat from his back. He greatly enjoyed his stay in Great Britain, and is enthusiastic regarding the treatment he received there. Wherever he went he was heartily welcomed.

— The headlong haste with which certain of our countrymen have accepted Pasteur and his hydrophobia inoculations as the heralds of a new era in medicine, has received a check, and from no less a person than Pasteur himself. The correspondent of the *Boston Herald* telegraphs, under date of January 4th, that the great chemist that day received a dispatch from the president of the Pasteur Institute in New York, asking if M. Pasteur would receive a medical man, who knew French, to study in his laboratory and learn his methods. M. Pasteur said: "These gentlemen are in too much of a hurry. It is premature to attempt anything yet. Wait until we see how the cases already treated turn out. Wait until we see how the Newark children get along. Wait, at least, until March, when the series of experiments, already commenced, will enable me to make known facts and data much more specific and detailed than anything yet published. Of course, I feel very much flattered to hear that Americans have thought fit to give my name to the institute, but in the pure interest of science delay is needed, as everything so far is merely experimental." "What answer shall you send?" M. Pasteur replied: "I shall telegraph, 'Vous allez trop vite.'"

NEW YORK.

— At a meeting of the Society of Medical Jurisprudence and State Medicine, held January 14th, the president, Dr. Frank H. Hamilton read a paper entitled: What are Legal Limitations of the Right of Private Judgment in Surgery; Does the Omission to employ Antiseptics justify an Action for Malpractice? The committee on cremation made a report strongly in favor of this mode of disposal of the dead, and presented a resolution recommending a bill for passage by the Legislature which provides that the bodies of all persons who die of contagious diseases, such as smallpox, yellow-fever and cholera, shall be cremated under the direction of the municipal authorities. Action on the resolution will not be taken until the next meeting.

— The graduating exercises of the Training School for Nurses attached to Bellevue Hospital took place January 14th, at the Nurses' Home, in East 26th Street. Mr. William E. Dodge presided, and Dr. E. L. Keyes delivered the address to the graduates, of whom there were twenty-four. The annual report showed that two hundred and forty four nurses had been graduated from the school during the past ten years, and that of these but five have died, twenty-two are married, and twenty-eight have responsible positions in hospitals as heads of training schools, matrons and chief nurses. One hundred and eighty-four still continue to practice their profession in hospitals or private families, and four of the nurses are connected with St. Paul's Home for Trained Nurses in Rome, Italy, where their services have been much appreciated by Americans visiting or permanently residing in the city. There is at present the full quota of students at the Bellevue school, sixty-four.

— The State Board of Charities held a three days' session in Albany, ending January 14th, and its annual report will shortly be presented to the Legislature. In it, it is stated, that there is no evidence of any considerable increase of pauperism in the State; but the increase in the number of the insane appears to be greatly in excess of that in population, and there is great necessity for further accommodations for this class. The evils arising from the shipment to this country, and especially to New York, of lunatic, imbecile, and otherwise infirm and disabled Europeans are fully set forth, and the conclusion arrived at that the remedy for this lies in the modification by Congress and more rigid enforcement of the Federal laws regulating emigration, by which these burdensome classes shall be effectually precluded from landing in America.

— The thirteenth annual report of the New York County Visiting Committee for Bellevue Hospital and other public institutions of the city calls attention to the fact that about 14,500 persons are now under the charge of the commissioners of charities and correction. Some improvements in the accommodations for these have been made during the year; but many others are still needed, and the prevalence of contagious ophthalmia among the children in the various institutions, due in great measure to imperfect quarantine, overcrowd-

ing, improper food, and bad drainage, as shown by the statistics recently collected by Dr. Derby and others, is especially commented on. A conspicuous example of overcrowding was found by the committee in the city female lunatic asylum on Blackwell's Island, which with a capacity for 1,250 patients, contained on October 1st, 1885, 1,629. "Trained nurses," says the report, "are greatly needed in the Bellevue Pavilion for the Insane. This pavilion is like a prison. No books, no occupation, not a strip of carpet, not a comfortable chair, not even a curtain to hide the grated windows." In regard to the condition of grammar school No. 6, on Randall Island, it says: "The absolute foulness of the air in which these apparently sickly children pass so many hours during the day beggars description. There is simply no ventilation whatever.

— An "American Pasteur Institute" has been organized, and among its incorporators is Professor Alexander B. Mott, of Bellevue Hospital Medical College. Its objects are defined to be "the gratuitous cure and treatment by the Pasteur system of inoculation, or such variations thereof, and improvements thereon, as science may develop, of all persons suffering from, or threatened with, or in danger of hydrophobia, or any other disease to which the system of inoculation may be found applicable, and the scientific examination of the causes, development, and improved means of prevention of hydrophobia and other diseases through inoculation or kindred methods." Dr. Billings, with the four Newark boys who have been inoculated by Pasteur, landed in New York from Havre, January 14th.

— A number of physicians have addressed a memorial to the Board of Health, requesting the latter to use its influence to secure the passage, by the Legislature, of an act which will protect medical practitioners, who, in good faith, report contagious diseases, against suits for damages, in case the affection does not prove of the character suspected.

— Mr. Am Ende, the Hoboken druggist who caused the death of two young ladies in August last, by compounding morphia in a prescription, in mistake, for quinine, has been acquitted, the defence being that the mistake was such as was liable to occur in any drug store, and that the defendant was suffering from overwork at the time.

— The reports of the Saturday and Sunday Hospital collection received up to January 15th, show the gratifying amount of $37,393.

— In consequence of the great reduction in the appropriation for the Board of Health for 1886 from $469,758 to $319,800, a large number of inspectors, sanitary engineers, clerks, and other officials, have been discharged; while the salaries of those remaining have been cut down about twelve and a half per cent.

— The report of the Board for the last quarter of 1885, shows that during that time, the sanitary inspectors made 85,934 inspections. 2,738 complaints of food adulterations were investigated, and 860 quarts of milk, and 173,719 pounds of meat and fish were condemned. The sanitary police made 29,256 inspections; 481 cases of contagious diseases were visited, 2,896 vaccination certificates were issued, 33,115 persons were vaccinated, and 81,429 was received from the sale of virus. Defects in plumbing and drainage were investigated in 25,660 cases. The report for the whole year, of Dr. Cyrus Edson, Chief of the Second Sanitary Division, shows that, in 1885, 7,006 specimens of milk were examined, and 1,701 quarts of adulterated milk destroyed. There were ordered destroyed, 72,700 pounds of candy, 540 pounds of head cheese, 37,905 pounds of canned goods, 5,160 pounds of cheese, 4,000 pounds of pickles, 212,000 pounds of fruit, and 790,410 pounds of meat and fish.

— There has been quite a serious epidemic of typhus fever in the Albany Penitentiary, and among its victims was the resident physician, Dr. Joseph W. Reilly, who died at his home in West Troy, January 15th, after two week's illness. Between December 1st and January 11th, seventeen of the inmates died from the disease.

— The fifteenth annual dinner of the Alumni Association of the Medical Department of the University, came off at Delmonico's, January 14th. Prof. J. W. Wright, in responding to the toast, "The Medical Department," said that the sum of $50,000 was needed for the erection of a building to contain a laboratory and dispensary, and a small medical and surgical hospital, and that one-half of that sum had been already conditionally promised.

Miscellany.

THE LATE DR. J. H. WHITTEMORE.

AT a meeting of the trustees of the Massachusetts General Hospital on the 9th inst., upon the announcement of the death of Dr. James H. Whittemore, late resident physician of the Hospital, a well-deserved tribute was offered by the chairman in the following "minute," which was unanimously adopted, and ordered to be spread upon the records of the trustees:

MINUTE.

The death of Dr. Whittemore is deeply felt by the trustees. They recall the high qualities which fitted him for the service of this institution, and which, in his long connection with it, were constantly ripening.

His energy, his quick response to every call upon him, his administrative ability, his seizure of every opportunity to advance the work under him, his independence, his sympathy and his comprehensive grasp of the interests in his charge, alike those of patients, attendants, nurses, officers, staff and corporation, were easily recognized by all his associates.

He served the hospital and asylum for twenty years: for half this time as resident physician of the hospital. Each year of his administration has borne witness to his power and fidelity.

Always ready to suggest improvements and to receive the suggestions of others, he carried out a plan once determined with signal ability.

The loss of his devotion to the hospital is not to be measured by words. It is to be appreciated hereafter even more than at present, and yet there is no one of us, even now, but fully shares in the sorrow for his departure.

Nor is thankfulness wanting, both for the honorable career that has been fulfiled, and for the peaceful ending of sufferings and anxieties borne with a cheerful fortitude above all praise. His memory will long be cherished by the officers and friends of the hospital he loved and faithfully administered to the very close of his life.

THE SALEM, MASS., HOSPITAL.

THE tenth annual report of this institution is issued by the Superintendent. The number of patients admitted to the Hospital during the past year was 140. Of these, 42 were medical, 98 surgical; 82 were males and 58 females. The average number of days passed in the Hospital by free patients was 32¼, and by those paying board, 13 4-7. Board was furnished to free patients 533 weeks, and to those paying board, 14 weeks. The Eastern Railroad bed was occupied 216 days, the Naumkeag Mills' 170, and the Salem Lead Company's 20, and 63 days' board was furnished to United States patients. The number of patients paying board was much less than in previous years, as, owing to the increase in the funds, the Trustees did not wish board exacted from any who could not easily afford to pay. Thus many were admitted free, who, in former years, would have been expected to have paid something, at least. The largest number of patients in the house at any one time, was 21; the smallest number, 8. The average cost of board was $2 per day. During the year, quite extensive additions have been made to the building of the hospital, and the trustees hope, the coming spring, to begin work on an isolated ward.

PROLONGED GESTATION WITH ANENCEPHALOUS FŒTUS.

THE prodigious size of many anencephalous fœtuses, says the *London Medical Record*, must have struck the most careless visitors to any large pathological museum; yet it does not seem to have been noticed, even by writers of monographs on teratology, with the single exception of Isidore Geoffroy St. Hilaire. Dr. Huber believes, from a case which came under his observation, that this abnormal bulk is consequent on a prolonged period of gestation. The case in question was that of an unusually intelligent and trustworthy woman, who stated positively that she menstruated last on August 15, 1869; first felt the fœtal movements on January 6, 1870, and was delivered on July 10, 1870, of an anencephalous fœtus weighing six Bavarian pounds. The fœtal movements, therefore, were felt on the 144th day, or 20th week of pregnancy, and delivery took place on the 327th day, instead of the 280th. The legal bearings of such prolonged gestation are obvious, and there is reason to think that prolonged gestation occurs more frequently than is commonly believed. Huber (*Klinik der Gebürtskunde*) reports two cases of 304 and 310 days respectively; and Löwenhardt, out of 245 cases, gives seven which extended beyond 305 days, as do Schlichting and others. In these, however, the fœtuses were normally developed.

LABOR DURING HYPNOSIS.

DR. EDWARD PRITZL announces in the *Wiener Med. Wochensch.*, a case of this kind, the first, he thinks, on record. The case is summarized in the *London Medical Record*, December 15, 1885. A young woman was under his care in a lying-in hospital who, he had reason to believe, would be easily brought into a hypnotic condition; and some preliminary trials showed his surmise to be correct. When, therefore, the case ultimately proved to be one in which narcotics should in the usual course be employed, Dr. Pritzl determined to give hypnosis a trial. In spite of her pain and the nervous excitement produced by the presence of several medical men, who wished to witness the experiment, the woman, after looking but a few seconds at the brilliantly illuminated thermometer bulb that was passed before her eyes, sank back unconscious. The following observations were made. The intervals between the pains lasted nearly two minutes; the pains themselves were more violent than is usual under a narcotic, and lasted on an average fifty seconds, being at their height actively aided by the pressure of the abdominal muscles, and the intensity of the latter was quite normal. The patient was perfectly insensible, but the left lower arm was cramped and the left leg became stiff. There was no change observable on the right side. She turned her head hither and thither as if she were angry, frowned and groaned. In the intervals, she resembled one asleep. In forty-five minutes from the time she became unconscious, a healthy child was born. In forty-five minutes after this, the woman was roused from her sleep, and would not believe she had been delivered, being hardly willing to own the child. The case up to the time of writing had taken a favorable course. Dr. Pritzl lays stress on the following points as remarkable. 1. It was easy to induce hypnosis in such a case as labor. 2. The pains were violent enough to arouse reflex action of the abdominal muscles but not to rouse the patient. 3. Evidently the hypnotic state accelerated labor; for it had been expected to last several hours. 4. The afterbirth stage, which lasted forty-five minutes, was remarkable for the character of the pains which, though short, were intense, and assisted by abdominal action; and the loss of blood was only about 300 grammes (mostly coagulated). Dr. Pritzl has similarly experimented in two other cases, which, though successful, were neither so rapid nor so perfect.

Correspondence.

HUMANIZED AND BOVINE VACCINE VIRUS.

PROVIDENCE, JANUARY 16, 1886.

MR. EDITOR, — I again ask permission to reply through your columns to the statements of Dr. S. C. Martin. I have no desire to enter into a discussion as to the relative merits of humanized and bovine virus. I simply wish to show that, with proper care a stock of humanized virus can be maintained with character unimpaired for a long series of years, and also to show how erroneous is the purely imaginary picture which Dr. Martin draws of the effects of the virus which is now in use by the Health Department of this city.

During the thirty years that this virus has been used over 47,000 persons have been vaccinated by this department, and not a single one of these has contracted small-pox, though the disease has many times been imported into the city and has spread among the unvaccinated. Yet the number of those thus vaccinated who were brought into most intimate contact with small-pox was very great. Dr. Snow who was for twenty-eight years Superintendent of Health, and to whom is due the credit of maintaining this stock of virus, bases his confidence in its protective power on the large number of such instances which he had observed and many of which he recorded. Over and over again he vaccinated persons immediately after exposure to

small-pox and who remained exposed to it, and found in every case that the typical vaccinia which followed proved perfectly protective.

To show that the symptoms which result from the use of this virus are very similar to those described by Jenner, as characterizing the disease, and very different from those which Dr. Martin theoretically thinks *ought* to be produced by this long humanized virus, the following description is given. It was written a week or two ago before Dr. Martin's graphic account appeared, by Dr. Charles H. Leonard, who has during the past fourteen years done 20,000 vaccinations in this city:

"After the insertion of the virus, the redness of the skin usually increases gradually until on the fifth or the sixth day it grows paler as a vesicle begins to form which by the eighth day has filled and covers nearly the whole of each scarification. It continues to enlarge until the ninth or tenth day and has a tendency to assume a circular form with a depressed center. The development of the vesicle is accompanied by considerable constitutional disturbance; the pulse is quick; the temperature rises from 99° on the fourth or fifth day to 101° or 102° on the seventh or eighth day; it then falls gradually, though the child is still feverish and chilly. The vesicles which on the eighth day were clear or translucent, on the next become turbid, and on the tenth day may become slightly pustular, and are surrounded by an areola which a day or two later is four or five inches across and may extend up to the shoulder, down to the elbow, and nearly around the arm.

"The vesicles begin to dry down by the twelfth day and at the fifteenth or sixteenth day will have solidified into brownish crusts while the surrounding inflammation will have greatly lessened or nearly disappeared.

"The crusts mature and fall off by the twenty-second or twenty-third day, yet they often adhere to the arm by their edges only, for several days longer. The crusts are roundish, mahogany colored, are thinner at the center than at the edges, and each leaves a broad superficial scar slightly depressed below the surface of the surrounding skin, and indented by numerous faveolæ."

In regard to a faveolated cicatrix not being indicative of a successful vaccination, that is, one which will protect against variola, I can only say that such a cicatrix has in this city been usually observed in those cases in which the protection was proved good by actual tests, while on the other hand, the deep smooth scar, admired by Dr. Martin, has been found on patients suffering from varioloid.

Yours truly, CHARLES V. CHAPIN, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 9, 1886.

Deaths reported 1,347: under five years of age 484; principal infectious diseases (small-pox, measles, diphtheria, and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 207, consumption 249, lung diseases 216, diphtheria and croup 95, scarlet fever 31, typhoid fever 16, whooping-cough 21, diarrhœal diseases 17, malarial fever 11, puerperal fever five, cerebro-spinal meningitis four, erysipelas four, typhoid fever three. From whooping-cough, New York 18, New Orleans two, Providence one. From diarrhœal diseases, New York 11, Boston and New Orleans two, each, Nashville and Cambridge one each. From malarial fever, New York and Baltimore four each, New Orleans three. From puerperal fever, Baltimore, New Orleans, Cambridge and Holyoke one each. From cerebro-spinal meningitis, New York two, Nashville and New Bedford one each. From erysipelas, New York three, Providence one. From typhus fever, New York three.

Cases reported in Boston: scarlet fever 40, diphtheria 21, measles 11, and typhoid fever three.

In 108 cities and towns of Massachusetts, with a population of 1,261,727 (population of the State 1,941,465), the total death-rate for the week was 16.98 against 18.18 and 15.63 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,906,446, for the week ending December 26th the death-rate was 19.3. Deaths reported 3,289: infants under one year of age 749; acute diseases of the respiratory organs (London) 383, whooping-cough 126, measles 122, scarlet fever 55, fever 30, diphtheria 24, small-pox (Liverpool, three, Bristol one), four.

The death-rates ranged from 13.6 in Brighton and 28.4 in Bolton; Birkenhead 26.3; Birmingham 17.3; Blackburn 23.6; Hull 15.1; Leeds 19.3; Leicester 14.2; Liverpool 22.4; London 18.0; Manchester 21.7; Nottingham 24.7; Sheffield 22.0; Sunderland 20.8.

In Edinburgh 21.0; Glasgow 25.; Dublin 22.8.

For the week ending December 26th in the Swiss towns, there were 31 deaths from consumption, lung diseases 22, diarrhœal diseases 11, whooping-cough five, typhoid fever four, puerperal fever three, small-pox two, diphtheria and croup two, erysipelas two, measles one, scarlet fever one.

The death-rates were: at Geneva 13.2; Zurich 13.6; Basle 18.9; Berne 27.3.

The meteorological record for week ending January 9, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Jan. 9, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 9, 1886, TO JANUARY 15, 1886.

MCPARLEN, THOS. A., colonel and surgeon. Now waiting orders in New York City, ordered for assignment to duty as medical director, Department of the Platte, on January 24, 1886. S. O. 5, A. G. O., January 7, 1886.

SWIFT, EBENEZER, lieutenant colonel, United States Army (retired). Died near Hamilton, Bermuda, December 24, 1885.

SOCIETY NOTICES.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK will hold its 80th annual meeting at the Common Council Chamber, City Hall, Albany, February 2d to 4th, 1886

BOSTON SOCIETY FOR MEDICAL SCIENCES. — A regular meeting of the Society will be held on Tuesday evening, January 19th, at the Harvard Medical School, at 7.30 P.M. Communications: DR. W. F. Whitney, "A Case of Fœtal Cretinism." Dr. J. W. Warren, "Preliminary Report on Experiments with Alcohol." Dr. Thomas Dwight, "Curious Anomaly of Nerves of Hand." Drs. Mixter and Newell, "Demonstration of new Injecting Apparatus." CHAS. H. WILLIAMS, *Secretary*.

NORFOLK DISTRICT MEDICAL SOCIETY. — A meeting for Scientific Improvement will be held at Room 7, Palladio Hall Building, corner of Warren and Dudley Streets, Roxbury, on Tuesday, January 26th, at 7.45 P.M. Communications: I. "Diphtheria," F. W. Vogel, M.D. II. "A Case of Femoral Aneurism," C. A. Bemis, M.D. III. "Epistaxis with Cases," C. W. Sparhawk, M.D. Refreshments will be served after the meeting.

S. ALLEN POTTER, M.D., *Secretary*.

ERRATUM.

In the Report on "Recent Progress in Ophthalmology," in the last number of the JOURNAL, page 31, for "Multiple Neuritis," read "Multiple Sclerosis."

APPOINTMENTS.

DR. W. B. GODSMITH, Medical Superintendent of the Danvers Lunatic Hospital, has accepted the appointment to succeed the late Dr. John W. Sawyer, as physician and superintendent of the Butler Hospital in Providence.

DR. W. A. GORTON, first assistant physician at Danvers has been appointed to the vacancy to be created by Dr. Goldsmith's resignation.

OBITUARY.

JAMES H. WHITTEMORE, M.D.

Dr. James H. Whittemore, for the past nine years resident superintendent of the Massachusetts General Hospital, died in Boston on the 6th of the present month, at the age of forty-six. Dr. Whittemore's professional life was passed in the service of the trustees of the McLean Asylum, and of the institution at which his death occurred; and most faithfully did he perform the manifold duties which devolved upon him. Conscientious, energetic, possessed of great executive ability and gifted with a frank and winning presence, he was peculiarly suited for the position of chief executive of a large hospital. His genuine kindness of heart was apparent to all who met him, while at the same time he conveyed a well-founded impression of firmness of purpose and thorough knowledge of his special work.

Constantly dealing with people of every degree and calling in life, he was liked and respected by all, and by none more than by members of his own profession. He was an eminently *satisfactory* man in his official capacity to all concerned — trustees, staff, patients, and the outside thousands with whom his duties brought him in contact. Socially he was genial and courteous, and as a friend he was loyal and kind. The disease, epithelial cancer, to which his death is due, necessitated the amputation of one wrist and the loss of a portion of the opposite hand nearly two years ago. He bore the pain which preceded the operation without complaint, and to the last kept up a brave heart in spite of unavoidable forebodings of still greater misfortunes yet to come. His courage was of the finest type, and differed as widely from that displayed in the excitement of battle as it did from the passive endurance obtained by use of opiates.

So long as consciousness remained he never failed to take an active interest in his immediate duties, and even found time to express sympathy for others whose burdens were but straws compared with his own. The large concourse of people of all ranks in life present at his funeral, bore testimony to the esteem with which he was regarded. No man in this community had more friends, and those friends were fairly won. His memory will be cherished as that of an honest, brave, and able man who did thoroughly good work in life.

THE PAVILION IN HOSPITAL CONSTRUCTION.[1]

BY ARTHUR C. HEFFENGER, M.D.,
Passed Assistant Surgeon, U. S. Navy.

IN writing this paper, I have purposely avoided entering into the details of ward construction, and confined myself, as much as possible, to general consideration of the true principles of hospital construction as exemplified in the pavilion system, and various ward types.

The field of hospital construction has grown to such immense proportions during the last twenty years, that it is only by the most careful selection and restriction that a paper, which aims at embodying its fundamental principles, short, yet satisfactory, can be prepared; so should facts appear to be too briefly stated, and a want of smoothness and fluency be manifest, I shall have to beg the leniency of the Society.

The present manner of sheltering and caring for the sick differs so widely from that in vogue a few centuries ago, that a comparison shocks the intelligence and humanity of our own times. In the middle ages, all institutions for the care of the sick in Europe, were in the hands of religious orders, who used them for their own profit and aggrandizement, and paid little attention to the suffering inmates. Indeed, this subordination of the welfare of the sick to the cupidity and rapacity of their religious masters became so notorious, Kurt Sprengel tells us, that the Council of Vienna, in the fourteenth century, ejected the ecclesiastics, and placed all institutions for the care of the sick under the jurisdiction of laymen. It was not till the sixteenth century, however, that St. Bartholomew's and St. Thomas's Hospitals in England, were put under lay management, and the Hôtel Dieu, in Paris, remained in priestly clutches till a much later period.

During those early days of the modern enlightenment, little, if any, consideration was given to the character of the buildings in which the sick were placed, or to their proper management, though Philibert Delorme, the noted architect and *protégé* of Catherine de Medici, who was the first architect of the Tuileries, realized the necessity of healthy houses, and in his *Traité Complète d'Architecture*, published three centuries ago, affirmed that ornamentation and elaboration of buildings in no way promoted their healthfulness, and that, therefore, they should give place to those structural features which contribute to convenience, health, and the ultimate prolongation of life. These excellent ideas of M. Delorme, unfortunately, made no impression, even upon the scientifically receptive minds of the day, and it was not till the eighteenth century, that earnest thought became directed to the crying necessity for a radical change in hospital construction.

The first great mind to clearly grasp this subject was that of M. Tenon, a member of the Royal Academy of Sciences, for it was he who originated the pavilion system, and thus brought to light the true principles involved in the construction of a healthy habitation for the sick. As the result of twenty years' laborious study, M. Tenon produced a great work, entitled "*Mémoires sur les Hôpitaux de Paris*," which excited so much interest in the Academy, that a committee was appointed, in 1787, to report upon it. The Committee, in their report, cogently set forth those studies and views of M. Tenon which eventuated in his proposed plan for a model hospital, the germ of the pavilion system of to-day; and I cannot better illustrate the ideas of this founder of modern hospital construction, than by giving a few extracts from this valuable report.

"M. Tenon, having thus first instructed himself by detailed investigations of all the hospitals of Paris, passes to a consideration of the Hôtel Dieu, which appears to be the principal object of his work, forming, as it does, the subject of the third and fourth memoirs, which are much more extended than either of the others. M. Tenon considers separately the buildings of the Hôtel Dieu and its dependencies, its furniture, its sick, and its attendants.

"In this examination, M. Tenon finds more to avoid than to imitate: there is useless multiplication of administrative offices, complication of administration, confusion of the departments, and an improper accumulation of sick in a space too small for the 3,400 patients which the Hôtel Dieu accommodates; calculating only four sick per bed, there are 2,600 in the single building of the Rue de la Bucherie, and on an area of 970 'toises'; 'the disposition of the staircases is bad; they are without air, and are infected. . . . . We will not enter into the details of the article which treats of the furniture, and we will only repeat a curious and interesting extract as to the convenience of placing three, four, and six patients in the same bed: the physical causes, from which the danger and sickness of the patient result, are developed thereby, and this result, which has been inferred from an extract in the first report of the Committee, is known to the Academy.

"M. Tenon devotes himself next to the dimensions of the wards, and shows that their length is regulated by the number of the beds, and their width by the eighth of a man, from which it results that for two rows of beds, the width of the wards must be 25 'pied'; lastly, that their height is regulated by the class of patient. Inflammatory diseases require high rooms; old or debilitated people, who require warmth, must have rooms less lofty. M. Tenon has devised a means of comparison, in this respect, of wards one with another; it is to consider the quantity of air each patient has to respire, and its circulation and renewal. The Hôtel Dieu, in confounding all the departments, and bringing together all classes of diseases, develops the cause of a frightful mortality, and has shown M. Tenon the necessity for the classification of these diseases, and for their separation, as much as possible. There are, above all, in the Hôtel Dieu, six classes which should be separated in a well-ordered hospital; those who are attacked with contagious diseases, lunatics, ordinary sick, wounded, pregnant or lying-in women, and the convalescent. . . . . M. Tenon proposes also to separate malignant fever and dysentery.

. . . . "The State has the greatest interest in caring for individuals in good health, but especially, wounded by accident, and mothers in the flower of their age, both of which renew the population. These two subjects have been treated by M. Tenon, with a care proportionate to their importance. He remarks and proves that everything which is essential to the wounded — pure air, cleanliness, and quiet — are wanting at the Hôtel Dieu. He asks that the wards for the wounded shall be well ventilated, kept clean, separated from any bad odors, and preserved from the noise of the house and the street traffic. He asks for wards for inmates

[1] Read before the Naval Medical Society, Washington, D. C.

in preparation for operation, wards to carry out the operation, and wards to achieve the cure. . . . .

"As for the lying-in cases, we will not repeat here the table which the notes and observations of M. Tenon (of which this memoir is the result), have enabled us to trace in this report to the Academy; we have shown to us the confusion of all the parts of this department, the want of air, damp, and all other causes of danger which threaten the lying-in cases. . . . . We could not, then, say anything on the mortality, which is the result of the bad arrangement of the Hôtel Dieu; we did not have the abstract of the registers. M. Tenon has procured it, and it goes over a period of eleven years. The result is to show that, whilst the mortality of the British Hospital is one in fifty-one, that of the Hôtel Dieu is one in fifteen and two-thirds, a frightful mortality, and which, alone, would necessitate the reform of the Hôtel Dieu, for it is as well to observe that it is not a question either of a period of epidemic, or where puerperal fever makes ravages. The mortality in these cases has often been half, and sometimes, nineteen out of twenty. M. Tenon, to remedy this mortality, proposes to entirely separate lying-in cases from the other sick — above all, from the wounded; to put a smaller number in the same wards; to ventilate these wards; to shelter them from damp and noise; to separate healthy pregnant women from unhealthy; and for the sake of morality, prostitutes from poor and honest women. . . .

"Above all, he recommends that the different species of convalescents should be separated — small-pox, itch, and all those recovering from contagious diseases. They should have their own separate promenades, and even their own wards.

"We had already announced this work in the report which we have made on the actual state of the Hôtel Dieu. . . . It is the fruit of a twenty years' study of hospitals, that the Committee had charged M. Tenon to publish. . . . We look upon this work as the most profound, and the most complete of its kind, and we believe it deserves, the approbation of the Academy, and to be printed under its privilege.

"At the Louvre, September 5, 1787. Lassone, Tillet, Laplace, Daubentar, Darcet, Coulomb, Lavoisier, Bailly.

"I certify the present extract to be conformable with the original, and the judgment of the Academy, at Paris, September 7, 1787.

"THE MARQUIS DE CARDORCET."

In the foregoing extracts, we see laid down the soundest principles of hospital construction and management; principles upon which, with but slight modification, the most modern hospitals are built and managed, though they were announced a hundred years ago.

M. Tenon seems to have been the first to clearly appreciate the necessity of proper form, dimensions, and arrangements of a ward. His rules for determining the dimensions of a ward are unique, and the idea of regulating the height according to the class of patients to be accommodated, deserves special mention. To him belongs the credit of laying down the law that every patient should have a generous and stated air-space, and that due regard must be paid to the proper circulation and renewal of the air furnished. He condemned strongly the pernicious habit (at the present day, almost impossible to credit), of huddling two, three, and sometimes six patients, into one bed, and finally forced its abolition. His subtle and masterly insight into the nature of wounds, and the parturient state, and his rules for the management of surgical and lying-in cases, challenge the admiration of the foremost thinkers of the day, for in spite of all the searching investigations of the last decade or two, we have not greatly outstripped this profoundly knowing Frenchman. It was he who first classified patients with scientific intelligence, and insisted that various groups of diseases should be separated as much as possible, that the sick might have every attainable chance for recovery, or, at least, not die from other diseases contracted in hospital. To fully carry out this idea of classification, separate buildings of sufficient size only to accommodate the patients of each group in a hospital of ordinary capacity, would be needed; and these buildings, judiciously situated with regard to each other and the administration building, would constitute the general hospital; and such, in fact, is the pavilion hospital of to-day.

The model hospital, which M. Tenon designed to illustrate his views, consists simply of two two-storied pavilions, indirectly connected by a central building of three stories. The pavilions are raised three or four feet above ground, and are built on vaults. The ground-floor ward in each pavilion, is of parallelogram form, and arranged to accommodate twenty-four patients, one being for men, and the other for women. They are warmed by stoves, and in the centre of each, is partitioned off a small room for a night nurse. On the first floor, these wards are divided into five, three of which are for women, and two for men. Of the women's wards, the first is for fever cases, the second for wounded, and the third for operation cases; and of the men's, the first is for wounded, and the second for operation cases. The ward offices are placed in small buildings attached to the free extremity of each pavilion. The central building connecting the pavilions, consists of an oratory on the ground floor, operating theatre on the first floor, and quarters for nurses on the second floor. The administration building is a long, low structure, placed a hundred feet in front of the pavilions, and is connected with them by corridors at either extremity. The only access to the hospital is through the centre of the administration building, a point strongly insisted upon by the projector. Many excellent arrangements are found in this building, but especially deserving of notice, are the receiving, dressing and bath rooms, and the disinfection chamber.

It seems remarkable that, notwithstanding the strong endorsement of the Academy, the advanced ideas of M. Tenon should have been permitted to lie fallow for over half a century, while not only France, but the entire world, suffered daily untold miseries for want of their application. But alas! this is one of many instances where the labors of great minds have preceded their century. It does not appear to have occurred, even to the Academy, that, for the benefit of mankind, the Tenon principles should be enunciated over the civilized world, and their practical application insisted upon at home; and it was not till 1839, that a project was originated by the *Assistance Publique* of Paris, to build a pavilion hospital, when M. Gauthier, the architect, was instructed to make his designs conform to "the suggestions issued in 1788, by the Commission of the Academy of Sciences, and the recommendation of M. Tenon, in his work on the construction of hospitals." This hospital was a long time under construction, and, after many modifications, was finally opened

under the name of "Hôpital Lariboisière,"[2] by Napoleon III, in the year 1853.

Although a magnificent structure, and greatly in advance of all other hospitals of the day, the Lariboisière cannot be said to have fully exemplified the ideas of M. Tenon. It is much larger than his recommendations warrant, for it ostensibly accommodates six hundred and thirteen patients, though really containing, at all times, at least one hundred more; the pavilions are too high, having three stories, where his design calls for two only, and are too close together; the wards are too large, and the water-closets offensively near them; and some of the pavilions are in objectionable proximity to the administration buildings. The systems of ventilation and warming introduced were excellent for the period, though far from satisfactory at the present day. The pavilions on the right are ventilated and heated by the systems of MM. Thomas, Laurens, and Grouvelle. Fresh air is forced into the wards by means of a fan, being partially heated as it passes over steam-pipes in the horizontal shafts, and further heated before delivery, by steam-stoves. Foul air passes out through vertical shafts. The air thus furnished, though sufficient in volume, is superheated, and, therefore, not wholesome for respiration. The pavilions on the left are ventilated and heated according to the system of M. Duvoir-Leblanc. The same horizontal and vertical shafts are used as in the pavilions on the right, but heating is done by the circulation of hot water, instead of steam, and an aspiration chimney, into which all the vertical shafts empty, draws foul air out of, and consequently, fresh air into the wards.

The Duvoir system furnishes air at a much lower temperature, though not in as large volume as the Thomas-Laurens-Grouvelle, and is much less expensive, both in first cost and maintenance. The drainage of the hospital has been bad from the beginning, and little has been done to improve it. The mortality has clearly demonstrated its many faults, and the fearful death-rate among the lying-in cases, finally forced the construction of a detached puerperal ward, after the system of M. Tollet. The Hôpital Lariboisière, though in many ways imperfect, has yet rendered most excellent service to the world by properly directing the course of modern hospital construction, which has evolved the splendid pavilion types of to-day.

(To be continued.)

THE CAUSE AND CARE OF CONTAGIOUS DISEASES.[1]

BY S. H. DURGIN, M.D.

I have not been fortunate in having a rare and interesting case or group of cases to report for my paper to-night, and have therefore selected a very common and practical subject. Contagious diseases have been known and described, so far as their physical and rational manifestations are concerned, more or less accurately since the days of our earliest writers on medicine, but it is not history, the peculiar physical appearances or the therapeutic treatment of these diseases which we shall dwell upon at this time.

It is rather the cause, care and prevention that we will discuss briefly. I hope to provoke discussion and ascertain how much uniformity of opinion there exists in the profession to-day as to the origin, care and prevention of these diseases.

The belief that disease is visited upon man by an angry Deity as a part of the plan, belongs to a remote age, although we would not be obliged to go beyond the limits of our own continent to find people still adhering to this heathenish delusion, and treating all interference to prevent the spread of epidemic and contagious diseases as attempts to antagonize the Almighty in his methods of disciplining men. This kind of ignorance and superstition coupled with an unwarranted prejudice against vaccination was shown in the recent epidemic of small-pox in Montreal.

I shall not attempt to speculate on the origin of the first case of any of the contagious diseases; I shall only remark, in passing, that there is no evidence to show that the first case was not produced by the same living, perfect organism that produces the same disease to-day. The first proposition I have to emphasize in my paper is that certain diseases are contagious and that they arise only by contact with a specific organism which comes directly or indirectly from a preceding case of the same disease. As examples of what may be called contagious diseases, I will mention small-pox, scarlet-fever, measles, diphtheria, cholera, typhus fever, typhoid fever, relapsing fever, yellow fever, puerperal fever, whooping-cough, chicken-pox and glanders.

Strictly speaking, some of these are contagious and some are infectious, but as the terms are generally used so interchangeably, I shall, for convenience, only use the word contagious. It is presumed that the great majority, if not all of you have seen sufficient evidence, either in practice or in the recorded history of the diseases named, to satisfy you that they are all contagious. A doubt is sometimes raised as to diphtheria, typhoid fever and cholera, but when we look over the vast amount of evidence recorded by careful observers concerning each of the three diseases, we cannot fail to recognize the fact that whatever positive evidence there is, is in favor of their contagiousness. Much negative evidence has been used by authors and by practitioners to show that typhoid fever particularly, was not contagious, but while we are not inclined to attach much importance to negative evidence when opposed by that of a positive character, we find by moderate observation and research that there is a preponderance of the latter over the former in favor of the contagiousness of all of the diseases named.

Some attribute the cause of typhoid fever to the decomposition of animal matter and especially to human, fæcal matters. Others say that sewer-gas produces it, while others say that typhoid arises from decomposing substances only when those substances are mixed with the germs of the specific typhoid poison. I find in the first volume of Ziemssen, after a discussion of the different views on this subject, the following: "Daily observation is sufficient to show that the decomposition of organic and excrementitious substances is not in itself sufficient to produce typhoid fever;" and again "We are forced to the conclusion that besides external conditions favorable to the development of the typhoid-poison, something else is necessary.

"The most convincing experiences show that typhoid fever never originates in any unusual amount of decomposing matter nor from any circumstances favor-

[2] So named in commemoration of the Countess of Lariboisière, who, about that time, gave her entire fortune to the administration of the Assistance Publique.

[1] Read at the Boston Society for Medical Observation, Jan. 4, 1886.

able to decomposition, but is always preceded by the introduction of a case of the same disease."

Dr. Sternberg, in speaking of the infectious diseases of the lower animals, says that "the infective agent is in each case a living microörganism known as 'bacteria' and belonging at the very foot of the scale of living things." He also says that "there is good reason for believing that the infectious diseases of man are also caused by pathogenic disease producing organisms of the same class. Indeed this has already been proved, for some of these diseases and the evidence as regards several others is so convincing as to leave very little room for doubt."

Dr. Billings, in his article on Hygiene in "Pepper's System of Medicine" says, "The diseases which spread by contagion until they form epidemics are those which have from the earliest times attracted the most general attention. They are also the diseases which have given rise to the most bitter controversies among medical men as to the means of their propagation and the best methods of prevention. Plague, cholera, yellow-fever and typhus are those with regard to which this difference of opinion has chiefly occurred, one party considering their chief cause to be contagion, or specific germs derived directly or indirectly from the bodies of the sick; the second party declaring that they are due to filth plus an unknown something, which is variously termed epidemic constitution, pandemic wave, Providence or X. The great majority of opinions at present is in favor of the view that they are all contagious, but not all, or always, contagious from person to person, that they spread from infected localities, which localities receive their infection from cases of the disease."

It seems to me that when we have arrived at a point where we can say that a given disease is contagious; that there is a something which passes directly or indirectly from one person suffering from a given disease, to another person and produces the same disease, and that this same process of perpetuating the disease has been going on for ages, that there is no material change in the character of the disease, that it is still governed in its appearance, progress and effect by the same laws which have governed it from the first, we are in a position where we can reasonably ascribe to this something which is so potent, so immutable in itself, and so unvarying in its effect, the character of a complete, living identity. Not the accidental product of decomposition, putrefaction, sewer-gas, filth, or of chemical action of any kind, but the product of its own simple parent.

It appears that the principal investigators in this field of research are arranged in two classes, one maintaining that chemical action alone is found in fermentation, putrefaction, contagion, etc., and the other that minute organisms are the cause and are indispensable to, all these processes. The one group has given us probabilities, theories and promises, the other, including such men as Koch and Pasteur, has given us practical and positive demonstrations in favor of the germ theory of contagious diseases.

The theory that any contagious disease can be caused by two or more different things is without any known demonstration and is opposed to all reason and analogy. There is no more reason to suppose that the soil or filth or sewer-gas can produce diphtheria, typhoid fever, or any other contagious disease, without first having been impregnated with the specific poison or germ from a preceding case than there is to suppose that corn or wheat may be produced from the earth without first having planted the proper seed. The fact that these diseases are so frequently associated with uncleanliness, with defective drainage, overcrowding and many other abominations, has made it easy to suppose that these conditions are the causes of the diseases while they are in fact not even necessary accompaniments.

From 1878 to 1884, 8782 cases of diphtheria were looked up by the Boston Board of Health and the premises where each case occurred carefully examined. It was found that over twenty-one per cent. of the premises were in a perfectly good sanitary condition. From 1877 to 1883, 3,659 houses were examined in blocks in different parts of the city, including the most recently built and best houses, and without reference to any reported cases of disease. It was found that defective drainage alone existed in forty-three per cent. of all examined. From 1881 to 1885, 2,896 houses where typhoid fever was reported, were examined, and twenty-six per cent. were found in good sanitary condition.

Some eight or nine years ago a large number of cases of diphtheria occurred in a cluster of houses in an outlying part of this city. Considerable alarm was felt by the people living there, and the sewer which ran through the place was vigorously condemned as the cause of the outbreak of the disease. I visited every family in which a case of the disease occurred, and examined the premises. I found scarcely any objectionable feature in the sanitary condition of the place. The sewer had a good pitch and was in good condition. Not all of the houses had any connection with sewers, but had vault and cesspool situated at a distance from the house. I found that the first cases occurred in the family of a milkman who lived near by and who supplied and delivered milk to nearly every family where a case had occurred. The milk and cans were handled in close proximity to the sick, and the small contaminated brook close to the house furnished the water for washing purposes.

The germs of cholera, yellow fever, typhoid fever and perhaps of others, find easy lodgment in the soil, in cesspools, vaults and drains, and a favorable pabulum and environment for their growth and multiplication. It is believed by some that the germs of yellow fever and perhaps of typhoid fever, after leaving the person must find lodgment in some suitable medium and undergo a certain change or development before they can produce the same disease in another person.

The difference in the course taken by these poisons, in their passage from person to person may be explained by the theory of a difference in their ponderability. Those of small-pox, scarlet fever, measles and typhus fever being light, pass readily through the air and give quick evidence of their contagious character, while the poisons given off from typhoid fever, cholera and yellow fever, being heavier, find their way from person to person more slowly, through the medium of water, soil, cesspool, vault or some other unclean material. It is known that in the *habitat* of yellow fever, persons occupying the lower floors of a dwelling or lying near the ground are much more liable to take the disease than those who use the upper floors.

It may be asked what advantage there is in giving up the idea that these diseases may arise from sewer-gas, drains, animal decomposition, etc., without the presence of the specific germ. I would say that it is easier, in a warfare of any kind, to deal with the enemy when we know where to look for it.

If we believe the origin of the poison to be in the drain, vault, cesspool or soiled earth, we are most likely to disregard the fact that the sick person is the source of an infinite multiplication of the poison. I would not detract a particle from the value of cleanliness or the necessity of care and treatment of all foul matters, but it seems to me that we should, if possible, recognize the true source of the enemy and direct our energies to the best advantage.

What are the most effective means for preventing the spread of these diseases? I believe that with almost universal consent of sanitarians we may say, absolute isolation of all cases, and the disinfection of everything that has become infected by a case.

The best form of isolation is without doubt in hospitals where the contagion may be concentrated and all means of communication between well and sick can be kept under control.

I would remove all such cases to a hospital except where proper isolation could be secured at home.

We have had an example in Boston, of what may be done with a contagious disease when the power and facilities for isolation are given.

We can but hope that the day is not far distant when we shall have the facilities for isolating diphtheria, scarlet fever, measles and many other contagious disease.

Can we depend upon disinfectants for the absolute destruction of these disease-germs, and if so, what are they?

The first question is well answered by Dr. Sternberg in a prize essay a few weeks ago, as follows:

"Evidence of disinfection may be obtained, 1st. From the practical experiments and experience of those engaged in sanitary work; 2d. By inoculation experiments upon susceptible animals; and 3d. By experiments made directly upon known disease-germs."

I think there can be no reasonable doubt as to the power of certain disinfectants to kill all living micro-organisms or disease germs. I believe that all bacteriologists agree as to this fact, but find a great difference in the power of some germs over others to retain life in the presence of the disinfectants.

The germ containing the spore is found to live where the germs without spores are readily killed.

According to Sternberg, there is no reason to believe that spores exist in the germs of cholera, smallpox, scarlet fever, diphtheria or yellow fever.

The agents found by experiment to be most useful in destroying disease germs containing spores are, fire, steam under pressure, boiling in water, chloride of lime and bichloride of mercury, and for those not containing spores, fire, boiling in water, dry heat, chloride of lime, solution of chlorinated soda, bichloride of mercury, sulphurous acid gas, carbolic acid, sulphate of copper and chloride of zinc.

Practically, it will be found best to destroy by fire such articles as are too badly soiled or worn to be of value; everything that may be wet without injury should be boiled in water for at least one hour; articles which cannot be wet without injury should be fumigated with burning sulphur, or subjected to the action of superheated steam. Three or four pounds of sulphur to each 1,000 cubic feet of space should be burned as rapidly as possible with the room tightly closed, and all articles therein so scattered and hung about as to permit easy access of the gas. The room should remain closed at least six hours.

To disinfect by steam, the articles should be hung about in the tightly closed room, and the temperature raised to 230° F., and held at that point for ten minutes, or 220° F. for fifteen minutes.

Floors and other hard surfaces may be washed with a solution of mercuric chloride (one drachm to the gallon of water) or a solution of the fresh chloride of lime, four ounces to the gallon of water. Nothing should be carried from the sick room before being disinfected. Articles which can be wet may be placed in one of the above solutions, kept in a wooden receptacle until such time as they can be removed for boiling.

All discharges from the bowels, bladder or stomach of patients suffering from typhoid fever, cholera or yellow fever should be received in vessels containing one of the above solutions in quantity greater than the infective material itself, and thoroughly mixed before being disposed of.

Gargling or spraying the diphtheretic throat frequently with an active disinfectant and frequent bathing or oiling the skin of the scarlatinal patient may measurably prevent the escape and dissemination of the poison.

SUBLUXATION OF THE RADIAL HEAD IN CHILDREN.[1]

BY H. W. CUSHING, M.D.,

Surgeon to Out-Patients, Carney Hospital.

THE cases to be reported, seen soon after the publication of Mr. Hutchinson's article on this subject,[2] illustrate very well the lesion described by him, and furnish examples of an injury producing an obscure, and, at times, puzzling group of symptoms.

An accurate diagnosis of injuries to the elbow joint, especially in children, is often a difficult problem to solve, and any addition to the surgeon's knowledge of these lesions, which will enable him to diminish the number of cases he is forced to class under the oft-times unsatisfactory diagnosis of "sprain of elbow," is gladly welcomed. And this lesion appears to be a correct explanation of the group of symptoms about to be described.

The injury is apparently much oftener met with than the brief mention of it in surgical text-books would lead one to suppose. A large proportion of cases are patients five years of age, or under. Hutchinson states that he was unable to produce it experimentally in subjects over five or six years. Lindeman,[3] in his report of twenty-four cases, finds all under five years, and a majority between nine months and two years.

In most cases it is the result of a sudden traction on the extended upper extremity, such as a child receives who, led by the hand, stumbles, and is prevented from falling by the jerk with which its nurse restores it to an upright position. The same conditions obtain when a child is dragged along by the hand, as is frequently seen, or lifted over an obstacle, or into a chair or vehicle. This explains why so many of these cases are found in children under five years of age, since this is a period of life during which the custom of lifting or leading children by the hand causes frequent

[3] British Medical Journal, December 5, 1885, Sydney H. Lindeman, M.R.C.S.

exposure of weak and incompletely developed articular structures to violence of the nature just described. This lesion is also said to result from a blow or fall received on the posterior surface of the semi-flexed elbow, which forces the head of the radius directly forward, but this is probably of rare occurrence.

Opinions differ as to the manner in which this lesion is produced. The sudden force applied to the fore-arm in these cases causes a displacement of the radius downward, so that its head is withdrawn from the orbicular ligament to a greater or less extent.

Mr. Hutchinson's article contains the only report of a dissection of this lesion that I have found, and is briefly as follows. He calls attention to the shape of the radial head; and to the difference in depth and contour of the radial and ulnar sides, the former of which is a rounded surface, while the latter is rectangular in outline.

These surfaces and angles, he concludes, play an important part in replacing the head of the radius within the orbicular ligament by their change in position during supination and pronation. He found by experiment that in subjects under five or six years of age, forcible traction during supination causes a slipping up of the orbicular ligament, with or without rupture of the suborbicular membrane or capsule. This was demonstrated by dissection, and he believes that the lesion consists, in most cases, in an escape of the head from the grasp of the orbicular ligament. In these cases, where the force is great, there is also probably a rupture of that part of the capsule connecting this ligament to the neck of the radius. As shown by his figure, the dislocation is a partial one, and the radius is still more or less in contact with the lesser sigmoid cavity.

Lindeman thinks the tendon of the biceps, one of whose actions is flexion and supination of the forearm, is an important factor in causing the displacement, and pulls the radius forward out of its position.

The anatomical arrangement of the articulation seems to indicate that the lesion is produced as follows: The force applied at the wrist by traction on the hand affects the radius mainly, since that bone occupies a greater portion of this joint, and is transmitted through it to the elbow, where the radial head is held in place by a group of ligaments, of which the anterior and external lateral act as guys to the orbicular, which in turn, holds the radius in its normal position. The orbicular is itself attached to the radial neck, and this is the weakest point in the structure. In the position of the joint in which the accident occurs, the posterior fibres of the external lateral ligament are relaxed, and the tense anterior ligament, with possibly the anterior fibres of the external lateral, is the one which is left to support the orbicular against the traction from below, which it is strong enough to do. The force is thus directed to the insertion of the orbicular about the radial neck, at the anterior portion of its circumference; this yields, and a subluxation is the result.

The direction forward which the radial head almost invariably takes, is probably due to the yielding of the ligament at this point, and possibly also to the traction of the bicipital tendon. The extent of displacement varies with the elasticity of the tissue, and the rupture or non-rupture of the orbicular insertion. The rupture occurs anteriorly, since, as just stated, the anterior ligamentous attachments are tense in this position, and the force is exerted here first, while the posterior structures are relaxed. This change of position of the radius causes the traction to be transmitted to other structures, and further injury is avoided. The weakness and elasticity of infantile tissues is probably the explanation why this lesion is so uncommon in adults, where such mobility of osseous structure is absent, and such an injury would cause a "sprain" only.

The clinical history is that the patient is injured in a majority of cases, as above described. Often a click or thud is noticed, or something is felt to give way, by the person holding the child's hand. The patient cries with pain, and the arm drops motionless to the side, with the elbow semi-flexed, and the hand partly pronated. The attendant is frequently puzzled to determine whether the wrist, elbow, or shoulder is the seat of the trouble, the latter being often designated as the location of the lesion. If the subluxation is reduced, either spontaneously or unconsciously by the parent during passive motion or other manipulation, all symptoms suddenly vanish, and nothing remains except a slight tenderness over the radial head, which soon disappears. If unreduced, the pain and impairment of motion persist, and medical aid is sought.

From a physical examination of the patient the surgeon usually obtains the following data: The injured arm hangs motionless by the side, with the elbow somewhat flexed, and hand semi-pronated. Attempts to use the latter, cause marked pain. Surface changes are usually absent, unless the accident was of such a nature as to cause additional lesions. No deformity exists except when the subluxation is marked, in which case the projection of the radial head causes a slight prominence below the external condyle on the anterior surface of the elbow. Tenderness over the head of the radius is the most constant symptom. In some cases, an increased surface temperature exists, with slight swelling. By careful manipulation, the projecting edge of the radial head can be felt, but it is easily overlooked, and the joint appears perfectly normal so far as its anatomical details are concerned. In some cases, flexion and extension are painful, but usually supination only causes discomfort. In most cases, supination alone is limited apparently by a mechanical obstacle. If not reduced by the above manipulation, the arm drops back into its former position, a symptom considered by Goyrand as pathognomonic.[4] Limitation of other movements of the elbow, if present, is due to muscular resistance.

If untreated, or the affected articulation is imprudently used, the pain and tenderness become more marked, and it is not improbable that the commencing periostitis or synovitis may transform what was originally a simple injury into a lesion, which results in the destruction of a joint. When the intimate relation of the injured tissues to the periosteum of the radius and the synovial membrane of the elbow is considered, this seems quite possible, and, as Mr. Hutchinson suggests, this may explain the mysterious origin of many cases of chronic arthritis of the elbow in children.

The rapidity with which all symptoms vanish after reduction, a thing which frequently happens unexpectedly during examination, is a striking peculiarity of these cases.

The diagnosis lies between sprain and dislocation, other injuries to the elbow joint being easily elimi-

[4] Boston Medical and Surgical Journal, September 18, 1862, R. M. Hodges, M.D.

nated, and the weight of opinion being opposed to Goyrand's theory that the symptoms are due to a displacement of the interarticular fibro-cartilage of the wrist in front of the carpal extremity of the ulnar.[5]

The diagnostic points are: the source of the injury; the localized tenderness; the limitation of supination only, and the rapid relief following reduction. The rotation of its head is apt to give the impression that the radius is in its normal position, and the surgeon is at a loss to account for the limitation of supination, which is almost the only abnormality discovered. And his perplexity is not at all diminished when he finds that suddenly all symptoms have disappeared as if by magic, leaving no trace of their previous existence.

The prognosis is generally good if the reduction occurs spontaneously, or the case is promptly treated. A majority of the patients probably recover without difficulty, but, as in other dislocations, a displacement may recur. The danger is from inflammatory processes being aroused by the imprudent or excessive use of the articulation directly after the injury, and I believe that quite serious trouble can follow such neglect or carelessness. Case V, in which a localized synovitis was apparently present, illustrates this, and the cases reported by Mr. Hutchinson have apparently led him to the same conclusion.

The treatment of these cases is easy. The movements of the patient, the manipulation of friends, or the examination of the surgeon with reference to diagnosis, often render further trouble about reduction unnecessary. It is, however, usually accomplished without difficulty by first semi-flexing the elbow, in order to relax the bicepital tendon, and approximate as closely as possible the displaced ligament and the edge of the radial head. Then with the forearm grasped by the left hand, supinate steadily with the right, while the left thumb over the radial head pushes in a backward direction. With a slight click or thud, the obstacle to supination suddenly yields, the head is felt to slip back into place, and the movements of the joint become normal.

In a recent article[6] it is claimed that flexion of the elbow to, or a little beyond, a right angle combined with full pronation of the forearm, is an easier and surer way to reduce the displacement; for the part of the radial head opposed to the curve of the orbicular ligament during pronation, is its thin rounded edge, over which the ligament easily slips; while full supination, by presenting a deep edge with a rectangular contour, renders reduction more difficult.

The after-treatment varies according to the symptoms presented. Rest is the most important factor. When slight tenderness, with or without pain, alone exists, as in spontaneously reduced cases, or unreduced ones where the arm has been kept quiet, rest in a sling for twenty-four to forty-eight hours prevents subsequent trouble. Here the displacement was probably quite limited, and the injury slight.

In cases complicated by contusions or secondary inflammation, with swelling, marked tenderness, and pain, rest is absolutely necessary. The elbow should be fixed by an internal angular splint, and the subsequent treatment should be that usually employed for sprains or other dislocations, and their possible sequelæ.

In marked subluxations, extension of the elbow should be avoided for at least two weeks after the injury, so as to allow the ruptured ligament to unite; otherwise risk of causing a fresh dislocation by the action of the bicepital tendon will be incurred.

It is not improbable that occasionally these dislocations remain permanently unreduced. In such cases, unless fixed by resulting inflammatory changes, one would expect considerable mobility of the radial head. This would account also for a slight abnormal projection met with in adults. Mr. Hutchinson reports two such cases. Lindeman has seen several patients where permanent enlargement of the elbow has resulted.

The cases alluded to at the commencement of this article are the following:

Case I. —— —— aged four, was brought to the Surgical Out-Patient Department of the Carney Hospital with the history that, on the preceding day, while being dragged by the hand, she had suddenly cried out as if in pain, and when released, was unable to use the arm, which was held motionless at the side. Pain followed all attempts at passive or voluntary motion. On the following morning, the symptoms had disappeared, and when examined at the Hospital, the only trace of an injury was a slight tenderness over the head of the right radius which, two days later, had also vanished.

Case II. —— —— aged three, was injured September 12th, 1885. A baby carriage, behind which she was standing, with its post-transverse bar grasped by both outstretched hands, was suddenly jerked away from her. She cried out at once from pain. The arm was seen hanging stiffly by the patient's side, and any attempt at examination or passive motion was resisted. Seen at the Hospital thirty-six hours later, unable or unwilling, on account of pain, to move hand or elbow. The left arm was held by the side with the elbow somewhat flexed, and the hand semipronated. The patient's efforts were apparently directed to prevent motion of the elbow joint. Comparison by inspection with the right elbow gave negative results. By palpitation a slight tenderness over the radial head was found. Passive motion showed the movements of the elbow unimpaired except that of supination whose arc of motion was limited to one-half its normal extent, although the head of the radius apparently rotated freely. Passive motion also caused pain, especially marked during supination. It was also present to a moderate degree during flexion and extension. During examination, while the elbow was held semiflexed, and the writer was trying to ascertain the exact position and arc of rotation of the radial head, the latter was suddenly felt to change its position with a peculiar sensation, resembling that felt during the reduction of a dislocated humerus as the head slides into the glenoid cavity, and at once the articulation recovered its normal extent and freedom of motion. This change occurred during supination, and only a slight amount of force was exerted when the unexpected reduction occurred. The arm was confined in a sling for forty-eight hours, and the patient was then discharged with a perfectly normal joint.

Case III. —— —— aged four, was treated at the Boston City Hospital by Dr. H. L. Burrell, to whose kindness I am indebted for the necessary data for this record. The patient was injured on the preceding evening, while being lifted by the hand from the floor to a chair. The symptoms reported were pain, not localized by the parents, and that motion of the arm was avoided by the patient. No treatment. When

[5] L'Union Medicale, November 23, 1861, Goyrand of Aix.
[6] British Medical Journal, January 2, 1886. J. Hutchinson, Jr., F. R.C.S.

first seen at the Hospital, eighteen hours after the accident, the above-reported symptoms were present. The arm hung by the side as usual, in the characteristic position. There was no change in the surface or contour of the limb. Tenderness over the radial head; supination limited one-third, and accompanied by pain. Other motions of the elbow normal and free. No deviation from the normal anatomical relations of the joint noticed. Reduced unintentionally by supination (elbow extended), while being examined to ascertain the position of the head of the radius. Treatment: sling for forty-eight hours. Discharged well.

CASE IV. —— —— aged six, also a patient of Dr. Burrell, was injured by being seized by the left hand, and swung around. Inability to use the arm caused the mother to suspect an injury to the shoulder. Pain considerable, but not located. No especial treatment. Two days later, the father, while "pulling" the arm, felt something suddenly "snap," and the patient's condition was much improved. Seen at the Hospital the following day. Position of arm normal. No deformity or surface change except a slight swelling below the external condyle. There was a slight tenderness and increase of surface temperature at this point. Motion of elbow normal except a slight limitation of supination from muscular resistance. Treatment: internal angular splint, sling. Apparatus removed four days later, and patient discharged. Recovery perfect.

CASE V. —— —— aged eleven, was a patient of Dr. G. H. Monks, by whose courtesy I saw the case. On October 3d, 1885, the patient fell eight feet between a wharf and a vessel, into the water. Was seized by the hand, and pulled aboard the vessel. He received an injury to the right elbow, either by striking it on a log used as a "fender," which was floating between the vessel and the wharf, or by a wrench received while being drawn out of the water. He complained of pain, referred to the elbow, tenderness and impairment of motion. The injury was followed by moderate swelling about the joint, with ecclymosis and superficial abrasion on its flexure surface. Treatment: rubbing with liniment. Condition improved. A few days later, after prolonged playing with "clappers," a performance requiring pronation and supination of the hand in rapid succession, the patient became much worse. The pain increased, and motion of the elbow became quite limited. Was first seen by Dr. Monks at the Carney Hospital October 17th, two weeks after the injury. On the flexure surface of the elbow was the fading discoloration of an extravasation in the later stages of absorption, and a few crusts covering a healed abrasion of the skin. Inspection negative, except, perhaps, a slight puffiness under the external condyle. Marked tenderness, and an indistinct "doughy" feel about the head of the radius. Flexion of elbow diminished one-half, extension one-fourth, pronation normal, supination not especially limited, but painful. Diagnosis: subluxation of the radius with contusion, reduced spontaneously and followed by circumscribed periostitis or possibly synovitis, resulting from imprudent or excessive use of the affected part. Treatment: internal angular splint, sling, cold application to articulation. October 19th, the swelling had disappeared, and the tenderness was much diminished. No pain, and arc of motion increased. The patient continued to steadily improve. Apparatus was discontinued five weeks later, and after carrying the arm in a sling for a few weeks longer, he was discharged nearly well. When last seen, January 5th, 1886, there was some tenderness over the anterior surface of the radial head when the hand was supinated, and a slight limitation of flexion of the elbow. Pain follows excessive use of the joint, but the patient has no trouble if this is avoided.

CASE VI, also a patient of Dr. Monks, resembles Case I so closely that a detailed history is unnecessary. The injury occurred in August, 1885, from the patient being dragged along by the hand. Reduction had already taken place when first seen at the Dispensary. A slight tenderness over the head of the radius was the only abnormal condition found, which soon disappeared, and when last seen, the patient was perfectly well.

RECENT PROGRESS IN MENTAL DISEASE.

BY HENRY R. STEDMAN, M.D.

CEREBRAL AND PSYCHICAL DISORDERS ASSOCIATED WITH LOCOMOTOR ATAXIA.

SEVERAL observers have very recently been engaged in working out independently the relations between cerebral disease (structural and functional) and locomotor ataxia.

The fact that symptoms of cerebral disorder as important and varied as vertigo, congestion and epileptiform attacks, aphasia, hemiplegia, etc., are not uncommon in the preataxic stage of tabes led Fournier [1] to the natural conclusion that psychical disorder might also be present under the same conditions. In corroboration of this view he finds in his notes seventeen cases in which mental complications have appeared in this stage of the disease. He reports as samples three of the cases. One was characterized by mental enfeeblement, loss of energy, fatigue on slight mental exertion, together with dulness and depression. This state lasted about a year, and then suddenly disappeared. A second case developed strange fancies, poor memory and a depressed, morose and hypochondrical state of mind with suicidal ideas. These symptoms also disappeared entirely and gave place to others of the usual tabetic variety. The third case was ushered in by two classes of symptoms, namely, disorders of sight and myoses and mental disturbance, almost identical in kind with that of the first case; mental inactivity and enfeeblement. The psychical symptoms were not of long duration and seemed to yield to specific treatment. Several years later a new set of symptoms more plainly tabetic, supervened, and finally tabes dorsalis of the classic form developed. The transient nature of these attacks will be noticed. They may also be compared pathogenically to the motor manifestations of tabes, such as ocular paralyses, etc., which are not uncommon in the preataxic stage.

In addition to these passing attacks there are also permanent disorders of the intellect in this stage. The tabes in these cases is marked by an assemblage of psychical symptoms resembling ordinary general paralysis, or more accurately that instructive group of cases which M. Fournier has described as pseudo-general paralysis of syphilitic origin. Mental symptoms of this kind, however, do not develop at the very outset, but usually after unmistakable signs of the locomotor

[1] L'Encephale t. 4, 1884, p. 641.

ataxia have appeared. Its chief features are, in brief, impaired memory, alteration of character, disposition, habits and morals, finally mental weakness and incoherence culminating in terminal dementia. He reports in this connection a remarkably complete case of what he terms cerebro-spinal tabes of cerebral origin, in which symptoms nearly identical with typical general paralysis ushered in and masked tabes dorsalis which in its turn manifested itself unmistakably, and finally the characteristic lesions of both diseases were found to be well-marked at the autopsy. There are also some very rare forms of transient mental disturbance complicating tabes; witness the delusional mania succeeding the lightening pains of the disease in the case reported by Dieulafoy, the melancholic stupor in the case of Burlureaux, and the melancholic frenzy of another case of Fournier's.

Beattey [2] has also reported within the past year investigations in this direction. His results, though not new, are interesting as corroborative of Westphal's recent results. He states that the study of the deep reflexes in general paralysis of the insane is exciting great interest among a small body of workers, their presence or absence tending to show that there is a close connection between general paralysis and other diseases such as tabes dorsalis, and affording to some extent a basis for classification of a disease which at present includes, in a common description, forms differing clinically and pathologically. Whatever may be the real nature of these phenomena, whether purely reflex, or merely local, the interesting fact remains that whatever increases or diminishes reflex action, generally increases or diminishes the phenomena under consideration.

In sixty-five of his cases of general paralysis, the knee jerk was considered normal in eleven, slightly exaggerated in eight, decidedly so in eighteen, diminished in five, and absent in eighteen. In five cases, the amount differed on the two sides. In the eighteen in whom there was no knee jerk, tabetic symptoms were not marked, being marked by the general paralysis. The latter was, however, in these cases of the demented type chiefly grand delusions, exaltation and excitement being generally absent or far from prominent.

The result of the autopsies in three cases of general paralysis, in which sclerosis of the spinal cord was diagnosed during life by the absence of the knee jerk, was, in each case, distinct sclerosis of the posterior columns of the cord throughout its entire length, extending, in one case, into the medalla oblongata. The sclerosis was most extensive in the lumbar region. He believes that this lesion will be found in most, if not all cases of general paralysis in which the knee jerk is markedly absent, and that although these cases are insufficient to prove a rule, they appear to him to confirm the indication of an organic connection between the two diseases.

Dr. R. M. Canfield,[3] in a recent lecture before the Hunterian Society of London, recalled the fact that Mickle had pointed out the close relation existing between locomotor ataxia and general paralysis, showing that they go hand in hand much oftener than could possibly be accounted for on the ground of simple coincidence. Quite a large number of cases were, he believed, soon to be published by a London gentleman confirming Mickle's observations. This seemed to him also to point toward the central character of the disease. Wilkes, he believed, had lately discarded the former pathology on grounds previously set forth in this lecture, but went so far as to say that this is no disease at all, but rather a collection of symptoms dependent on no localized lesion, and that they, collectively and individually, occur without any direct significance. Dr. Canfield thought it improbable that such a train of symptoms as we meet with day after day, bearing such a close relation to each other, and following such a decided course as these do, should not be dependent upon some definite pathology. True, the disease may rest upon the borderland of the so-called atrophic troubles, but it seemed to him that we must look to the motor centres themselves for its true genetic pathology, and perhaps we should come to recognize locomotor ataxia as a functional trouble.

[3] Lancet, July 18th, 1885.

THE ALLEGED FRAGILITY OF BONES IN GENERAL PARALYSIS.

The weight of opinion has long been in favor of an alteration of the bony system in general paralysis, occurring as an essential pathological element of that disease, and expressed by a marked tendency to fractures. This Christian [4] does not believe, although he does not dispute the diagnosis of asteomalacia in certain recorded cases of general paralysis. He denies, however, that osseous change of this nature forms a part of the systematic *ensemble* of that disease.

The arguments heretofore advanced have been based upon isolated cases and statistics. The employment of direct method of inquiry, namely: microscopic examination of the bony tissue of general paralytics — a simple and easy line of investigation has been strangely enough neglected. The cases hitherto reported he shows to be untrustworthy for want of exact diagnosis. The statistics of the subject are open to the same objection. Old fractures of the ribs are often met with which have occurred before the patient's admission to the asylum, and even before the disease began. Then, also, many are due to external violence, the amount and nature of which are not properly estimated. The different practices in regard to non-restraint in different countries and asylums, is another source of fallacy. Lander Lindsay, who has given special attention to the question, comes to the conclusion that if England is the home of non-restraint, it is also the land of fractured ribs in lunatics. In that country, most of the fractures of that class have been due to external violence. This fact of their frequency is imputed by their English alienists not to undue violence on the part of attendants, but to the diminished resistance of the bones, occasioned by the disease, and consequently osteomalacia is diagnosticated. The number of falls which general paralytics meet with in the course of this malady are as frequent as those of a child, and far less easily prevented. No other form of insanity is so prolific (excepting possibly epilepsy), and yet Christian, in his six years and a half among two hundred and fifty general paralytics, has not met with a single fracture in one of these patients. Ingels, of Gand, confirms Christian's statement, and adds that for twenty-five years that he has been in charge of the asylum at Ginslain, he has observed very few fractures, and almost never had he seen them in general paralytics. Morel, for seventeen years in

[4] Annales Medicales Psychologiques, November, 1885.

charge of the female lunatics at Gand, stated that he had met with *no* case of fracture of the ribs, and only three or four other fractures, one of which occurred in an ataxic patient.

GENERAL PARALYSIS WITHOUT INSANITY.

M. Luys has recently made a valuable contribution[4] to the subject of general paralysis without insanity. A somewhat detailed abstract of this paper is necessary, in order to clearly bring out the writer's instructive views on this mooted subject. The article is devoted to that entire class of cases met with, in which are present all the symptoms of general paralysis without insanity, who die in a short time, and reveal at the autopsy lesions which are identical in character with those of general paralysis (such as, for example, the excessive growth of the cerebral connective tissue) but which differ as to the region of the encephalon invaded.

In ordinary general paralysis with psycho-intellectual troubles, such as pronounced delusions, etc., and a train of somatic disorders, the morbid process is confined chiefly to the cortex, the seat of psycho-intellectual activity. The following cases, however, show by the plainest pathological characteristics that when the bodily element only is concerned, when the symptoms are motor ones exclusively, for example, impairment of articulation, purely automatic excitation with *secondary* enfeeblement of the mental faculties, it is not the higher or intellectual centres which are the seat of the disease but far different regions of the brain, namely, the base, those portions which are especially concerned in the expression of bodily acts.

Thus it will be seen that in disease as in health it is possible for these two portions of the brain to act independently of each other.

In the first case we have a woman of thirty-eight years, with no history of syphilis. In a few months she runs rapidly through the purely somatic phases of general paralysis, for while under observation the delusional ideas peculiar to complete general paralysis were never manifested. The malady in her case aborted, as it were. She manifested only the usual train of physical symptoms, tremor of all the limbs and of the tongue, next, progressive paresis attacking collectively the motor powers causing, in a short space of time, inability to walk) and compelling her to lie in bed, and finally complete paralysis of the sphincters. At the autopsy those portions of the nervous system which supply in the physiological state the motive power of the bodily functions were found to be in a state of advanced disorganization. The cerebellum was small, shrunken and sclerosed. Moreover, the sub-thalamic regions of the cerebrum (the locality of red nuclei of Stilling, the gray substance of Sömmering, the accessory bands) which receive the fibres of the superior cerebellar peduncles and which assist in the transmission of its intra-cerebral nerve force, these regions were the seat of sclerosed indurations which had destroyed the active elements of nervous power. The physical forces disappeared hand in hand with the inroad of the sclerosis and its obliteration of the centres from which those powers spring.

But the effect of the sclerosis of these regions was not confined to motor impairment. It had also led to the destruction of the transmission paths of sense impressions between these centres and the cerebral cortex. This is a complete and adequate explanation of the apathy, indifference and hebetude manifested as the case progressed, keeping pace with the progressive and rapid invasion of a portion of the thalamic region — a region which M. Luys still holds to be the true port of entry for sensorial impressions.

The absence of marked lesions, partial atrophies, etc., of the cortex and of adhesions of the pia mater as well as the rapid progress of the mental enfeeblement confirm the opinion that the mechanism of the dementia must be ascribed to the lesions of the lower but related centres spoken of, rather than to any destructive lesions in the cerebral cortex.

In the second case are found the same somatic troubles of general paralysis also originating in localized sclerosis of the regions of somatic activity at the base of the brain.

The patient was a woman of forty-six, rational on admission, but weak in body and mind, though able to give an account of her condition. The disease had lasted eight months, beginning with severe frontal headache. On admission profound asthenia obliging her to lie down constantly; tremor of tongue and hesitation of speech. She had not one delusional idea. She answered questions correctly, and for three months no sign of active mental trouble appeared, although she had a tendency to insomnia and would leave her bed occasionally. At these times she was a little disturbed and had the nightmare more or less. The mental manifestations were rather those of enfeeblement, her range of ideas being limited. This dementia, only impending when patient was first seen, made rapid progress and was nearly complete five weeks after her admission. At this time the muscular exhaustion was extreme and kept her confined to bed.

Her intellectual obtusion was so great that she could only with difficulty pronounce certain phrases in the form of guttural sounds, but they were correct and relevant ones. At same time and occurring chiefly at night convulsive phenomena developed. From this time these symptoms became rapidly more and more accentuated. The convulsions continued, the mind became almost blank, she required to be fed by tube, but to the last she was able to respond "yes" or "no" to certain questions, thus showing that the perceptive centres of the brain were not yet notably impaired. Manifestations of consciousness still appeared in the form of certain articulated sounds.

At the autopsy there were found no adhesions of the membrane nor marked softening of the cortex, and, in short, there were none of the usual appearances of general paralysis on the cortical surface. But at the base of the brain the red nuclei of the tegmentum and vicinity on both sides were indurated and stiff to the touch. In running the finger lightly over the indurated points their firmness in the less resisting and softer substance was plainly felt. The cerebellum was small and atrophied. The central fibres of the laminæ were thin, narrow and filiform, so much so that the central white substance was very markedly reduced. Cerebellar cortex somewhat thinned. The left corpus dentatum was very perceptibly hardened. It had the appearance of a stiff, reddish, embroidered pattern which stood out from the surface of the section. The structure of the pons was firm and indurated en masse. The olivary bodies had a wavy and rigid appearance in sections and felt like hard shells, also projecting above

[4] L'Encephale, November, 1885.

the surface of the cut. The bulb and its vicinity, as well as the pons was equally and markedly rigid, indicating the presence of numerous sclerous infiltrations. The surfaces of the fourth and third ventricles were greatly thickened and could be raised in pieces like bits of moist parchment. The subjacent gray substance was softened and intersected by numerous capillaries, careful microscopical examination of indurated parts showed that the fundamental lesion found scattered here and there through the whole extent of regions invaded consisted of an advancing hyperplasia of connective tissue forming in places depots of infiltration.

These observations show that if in certain cases the somatic troubles of general paralysis do not develop with a complete train of ambitions or hypochondriacal delusions. If the morbid process, so to speak, aborts and remains limited to the automatic centres it is because the higher centres of the brain remain comparatively intact and the morbid action becomes localized either in the spinal cord or in the regions at the base of the brain.

Dr. Savage [5] states that he has seen several who for years have exhibited bodily symptoms in every particular coinciding with those found in the patients in his asylum suffering from general paralysis of the insane, and yet without the slightest evidence of insanity, even without any loss of memory or of self-control, so that in fact, the patient was sound in mind although a general paralytic in body. The reason, he believes, that the condition has hitherto been misunderstood is, that asylum physicians rarely see cases in general hospitals; and general physicians only occasionally have the chance of watching true general paralysis. In his opinion, general paralysis may develop in any of its forms without mental symptoms for a considerable length of time, but unless cut short by some intercurrent or accidental cause, mental deterioration shows itself before the end. The symptoms may be only those of weak-mindedness, and may be so slight that comparatively little importance is attached to them.

SYPHILIS AND INSANITY.

Contributions to the relations of the above disorders to each other have been unusually frequent of late, the drift of opinion being toward decided scepticism as to the influence of syphilis in cases not only of general paralysis, but also of pure insanity in syphilitic patients. There is also but little difference of opinion as to the efficacy of antisyphilitic treatment in such cases.

The proceedings of a medical society in Berlin [6] a few months ago contain the latest view of this intricate question, and as most of the points involved are presented and by competent observers the account of the discussion is well worth perusal.

Mendel called attention to the fact that the Congress at Copenhagen in 1884, showed plainly enough that opinions still differed widely on the question of the relationship of syphilis and general paralysis. But for several years past observations have multiplied and these relations have become better established through most reliable statistics. It is clear that the statistics of large public asylums cannot be utilized, as patients treated there have their mental faculties, particularly the memory, too much impaired to enable them to say with any accuracy whether or not they have had syphilis ten or fifteen years previously. It is different in private asylums, for there the family physician, the parent's relatives and friends can give the necessary facts. In this way Reinhard, who is still not a believer in syphilis as a cause of general paralysis, has found that in the upper classes, general paralysis had been preceded in 73.3 cases out of 100 by syphilis, while in the lower classes he had found (probably from inability to obtain reliable statistics) but 16.7 out of 100 cases. It is through relying on statistics that certain authors deny all relation between syphilis and general paralysis, while others are equally confident that every general paralytic is syphilitic. The objections (aside from that of the inefficacy of anti-syphilitic treatment) which Mendel considers at all serious regarding a positive relationship of this kind, is that in general paralysis it is rare to meet with syphilitic lesions in other organs (he estimates that ten paretics out of one hundred will be found to have other organs also affected). But, on the other hand, the same statement holds true in cases of undoubted syphilitic cerebral lesions, gummata for example.

In order to demonstate the relationship in question, Mendel has had recourse to experimental investigation. He recalled in the first place certain recent experiments in which a dog fastened to a revolving table with the head toward the periphery and subjected to 130 rotations a minute. He died in about half an hour. On opening the head general hyperæmia and meningeal hæmorrhages were revealed. But in the case of an animal subjected to 110 revolutions in eight or nine minutes the process being repeated each day for a fortnight, all the symptoms of a cerebral affection were produced, namely, ataxia, paresis of the legs and of the muscles of the face, trunk and nape, change in his barking, and trouble with the urinary excretion. At death, several months later, after he had run through all the motor symptoms of a general paralysis, the lesions of this disease also were found, namely, pachymeningitis, chronic adhesive arachnitis, internal hydrocephalus and cortical intestinal encephalitis.

By investigations in the same direction Dr. Mendel endeavored to ascertain whether a moderate hyperæmia could not produce the same troubles after the walls of the cerebral vessels had been rendered more permeable. Following Popow, who has shown that corrosive sublimate produces alterations in the walls of the vessels of the cerebro-spinal system, he injected into a dog, each day for about a month, half a syringeful of a solution of 0.025 gr. of corrosive sublimate in 50 gr. of water. At the end of that time the animal was subjected to moderate rotation as above described for some minutes. He died four days later, and numerous hæmorrhages of the cerebral cortex were found. Another dog received for the same time three-fourths of a syringeful of the same solution and was left undisturbed for two months. He was then given each day from eighty to ninety rotations within three or four minutes. He died in five days with the symptoms of general paralysis. The reader, in applying these results to man, stated that in a large number of cases general paralysis had its prime origin in changes in the cerebral vessels, the walls of which, as had been demonstrated in the majority of cases of general paralysis, had become more permeable and under the influence of an active hyperæmia allowed the blood globules to escape, thus forming the starting of an interstitial inflammation. The vascular alteration may possibly, but by no means certainly, be due in some cases

[5] On Insanity and Allied Neuroses, 1884.
[6] Reported in Annales Medico Psychologiques, November, 1885.

to syphilis, in others to the excessive use of nicotine, alcohol, or mercury. This hyperæmia which these antecedent changes make possible and which give rise to the cortical lesions of general paralysis, may be due to excessive emotion, traumatism, intense heat, etc. Here we have all the factors which are necessary for the production of general paralysis.

It should not be surprising that no benefit follows syphilitic treatment in cases of this class, as the lesion is not a pure specific alteration but merely an inflammation resulting only partially from syphilitic change.

Dr. Westphal dissented from these views. He placed no value whatever on statistics, and declared that it was extremely rare to find syphilitic lesions at the autopsies of the insane, no matter what the form of mental disorder, and that the proportion of ten in one hundred was far too great. As, on the other hand, there were no characteristics by which syphilitic changes in the cerebral vessels could be recognized, all conclusions on the subject were premature. Moreover, Dr. Mendel had said nothing regarding the calibre of the vessels affected. The larger vessels were almost never involved in general paralysis, and as to the smaller ones, he had not even described the alteration they underwent, which was probably an hypertrophy of the tunica adventitia, a change which occurs under a variety of circumstances and which has not the influence upon the circulation which theory ascribed to it. As to violent emotions they figure as an etiological factor, not only in general paralysis, but in a number of other forms of insanity.

Hospital Practice and Clinical Memoranda.

FOUR CASES OF PLACENTA PRÆVIA.

BY OLIVER S. LOVEJOY, M.D., HAVERHILL, MASS.

CASE I. October 23, 1883, I was called in great haste to see Mrs. X., who was said to be flowing more than was good for her and needed assistance at once. The patient, I was informed, was about six or seven months along in pregnancy. She recently rode some twenty-five miles over a rough road, and had commenced flowing before she reached home. On examination found the placenta in the bed, but the child had not been expelled from the womb. The flooding had entirely ceased though there was a large quantity of blood in the bed. The womb had closed quite firmly over the child's head, and it occupied some time to remove the fœtus. This mother was well-developed, healthy and strong, and had had one child some two years previous. Had a good getting up and was none the worse for the loss of blood.

CASE II. January 6, 1884, had been to some distance to visit a patient and was on my way home, when called into a house I was passing to see a sick woman. The husband kindly informed me he guessed there was not much the matter, only the wife was a little nervous and thought she ought to see a physician. The woman was in bed; said she expected to be confined in a few weeks but did not think it was then time; had no labor pains but was flowing badly; had had one or two hæmorrhages before, but not so severe. She was a large woman, weighing about two hundred pounds. This was her sixth or seventh pregnancy, all former labors had been natural. On examination of the bed I should have said two or three quarts of blood had been already lost, though I was informed there were two gallons or more. On farther examination per vaginam, the placenta was found to cover the os completely, which was open to the size of a silver dollar, not rigid but flaccid; no membranes could be felt. The finger was passed through the centre of the placenta and the membranes ruptured. A very large amount of water escaped, immediately followed by a loop of the cord and hand and arm. I attempted to return the cord and arm, but most signally failed, and as the mother resisted every effort to do so, I sent to the city for an assistant and ether.

Very little hæmorrhage after the escape of the water. I plied the patient well with Squibb's fluid extract of ergot, but could get no labor pains. After assistance arrived I found the placenta hanging out of the womb. Removed it entire and separated the cord. Then without the use of ether turned and delivered. The child weighed something over ten pounds. On the fourth or fifth day after delivery called to see the mother and found her sitting up knitting a sock for one of the older children.

CASE III. August 13, 1884, was called to Mrs. X., in labor. Had visited her one month previously, at which time it was supposed labor had commenced. She was flowing badly at this first visit, and I was informed three or four floodings had occurred previously varying in time from two to four weeks. When I arrived at the bedside, found she had fainted dead away, and the bed was literally soaked in blood. Here was an entirely different case from the others, it being the first pregnancy and the patient a little bit of a woman, who in her *best estate* never weighed over ninety pounds, could ill afford to spare any blood, and was pale and chloroic at all times. The womb was but slightly open and the placenta firmly adhered about the os. The pains irregular, occasionally quite firm, then weak or entirely absent. In this case, as in the preceding one, the cord prolapsed and had ceased to pulsate. The child being evidently dead I concluded to deliver as soon as possible. I attempted to apply the forceps but the womb was not sufficiently open to do so. Opened the child's head and delivered. The mother was extremely prostrated from the great loss of blood, but before I left the house reaction had taken place and she did very well. Ether was given by an assistant.

CASE IV. November 6, 1884, 6 o'clock, A.M., received a note asking my assistance as soon as possible in a case of placenta prævia. The patient, a woman of some twenty-six or twenty-seven years of age, was in labor with her third or fourth child. She had had no pain and the womb was but slightly open. The flowing at this time was not as profuse as it had been at an earlier stage. The foot of the bed had been raised and the vagina was full of large firm clots of blood. The bed was full of blood, a large-sized vessel was one-fourth full, and I should think there was three pints in a slop-pail. The foot of the bed being raised had allowed the blood to flow back and there were not many dry threads in the garments on her person. She was plied with ergot and brandy as long as the stomach would retain them, and had fainted a number of times, and was almost pulseless. The cord as usual was prolapsed and had ceased to pulsate before my arrival. The os at this time was open to the size of a

half dollar and the placenta could be felt to one side. I opened the head and removed the child as soon as I could sufficiently open the womb. I did not attempt to use forceps for fear of another gush of blood, which would have been quite likely to have proved fatal. The patient made a good recovery.

In two of the above cases the placenta passed before the child, and with them the flooding ceased.

DILATATION OF PHIMOSIS.

BY CHARLES W. HARWOOD, M.D., OF WORCESTER, MASS.

About five weeks ago, H. S., a young man of twenty-four, came to consult me in regard to a phimosis. The prepuce, stretched to its utmost would allow a circle of less than three-eighths of an inch in diameter to be seen of the glans. As he contemplated marriage he was desirous of relief, but dreaded the operation of circumcision.

I had seen in the *British Medical Journal* (November 8, 1884, and January 31, 1885) articles upon this subject, the first of which articles has reappeared in *Braithwaite's Retrospect* for July; but as I was not able to procure readily the instruments described, I improvised one which, though ludicrously simple, perfectly answered the purpose.

It was made from an ordinary clothes-pin. I split the pin through to the end, and, cutting away to a proper angle the inner side of the shorter arms, I had twin levers of the first class, which a rubber band at the point of bearing kept together. The ends and edges of the longer arms were carefully filed smooth. I also provided half a yard of elastic cord which, when wound around the shorter arms, gave the necessary power.

I inserted the well-oiled ends of the longer arms between the prepuce and glans, and found that I could obtain by my rubber cord any degree of dilatation; but the stretching was far from being so painless as one of the correspondents of the *Journal* asserts. Accordingly, before my next trial I applied the four per cent. solution of cocaine, using four drops, and after ten minutes four more. Then waiting ten minutes longer, I inserted the instrument and dilated the foreskin readily, and without causing the slightest pain.

I repeated the operation twice a week, and now the prepuce easily passes over the glans.

The instrument costs altogether less than five cents, and as it will accomplish its work readily and painlessly (thanks to cocaine) I have thought it worth presenting to the notice of the profession.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL OBSERVATION.

H. L. BURRELL, M.D., SECRETARY.

January 4, 1886, Dr. E. M. Buckingham in the chair.

Dr. H. W. Cushing read a paper on

SUBLUXATION OF THE RADIAL HEAD IN CHILDREN.[1]

Dr. Fifield said that the subject of the paper was one that had excited discussion for a long time.

[1] See page 77.

The injury occurs in both adults and children. In adults the cause is a fall upon the hand which may occasion displacement of that member anteriorly or posteriorly. In children the cause is due to lifting the child by the arm or hand.

There have been two autopsies in children; one where the head of the radius was found resting on the outer condyle; in the other a portion of the cap of the radius was found broken. Sometimes it is impossible to reduce the deformity.

As early as 1837, Gardner, and at the same time, Goyrand of Aix, investigated the subject and both said that the dislocation was due to a displacement of the triangular fibro-cartilage at the wrist-joint.

One theory that has been advanced to explain the deformity is, that the projection on the radius is hooked beneath the ulna, until strong supination is made; but this is untenable, owing to the distance between the bones being too great. It has been thought that the turn of the head of the radius upward carried with it a portion of muscle that produced the dimple so often seen.

Dr. R. M. Hodges has written a paper upon the injury, which had been accepted as an authority.

Dr. Fifield spoke of the extreme ease with which the deformity could be reduced; at times the head of the radius actually slips back while the surgeon is examining the patient.

An injury which was extremely liable to be confounded with a dislocation is "paralysis from twist or sprain;" in this injury there is of course no sub-luxation but the arm hangs limp at the side.

The diagnosis is said to rest upon, the head of the radius being felt in its normal position in the "paralysis from a twist or sprain."

Dr. McCollom had seen three cases of the injury; the first went back very easily and quickly; the others were etherized, on account of the painfulness of the examination, and were then easily reduced. In the last case there was a marked swelling. The first case was treated with a simple figure-of-eight bandage but the others were immobilized for a little time by an internal angular splint. He called attention to the custom of nurses and parents carrying children across walks, etc., by seizing and lifting them by the arm.

Dr. Spear said that he could emphasize the statement made by the reader that all cases do not recover spontaneously. He described a case where there had occurred a dislocation of the head of the radius which had been followed by partial anchylosis preventing the individual from carrying the hand to the head.

In some English publication he had seen that an osseous outgrowth from the injured periosteum was the cause of limitation of motion at the elbow-joint. He considered that this arm was an example of that condition. In the arm he spoke of, the rotation was perfect but the flexion was impaired by osseous outgrowth. He inquired if the reader had found any recorded cases where this osseous outgrowth had taken place.

Dr. Cushing said that Hutchinson had reported an acute osteitis following the injury, and that permanent enlargement of the elbow-joint is mentioned by Linderman.

Dr. C. P. Putnam spoke of a case where the dislocation had recurred five or six times in a few years. The dislocation had been so easily reduced that the parents of the child had sometimes reduced the luxation.

DR. S. H. DURGIN then read a paper upon

THE CARE OF CONTAGIOUS DISEASES.[2]

DR. A. H. NICHOLS remarked that while it was true that a few authorities (like Murchison) believed that certain zymotic diseases might be generated by the introduction of filth in a state of fermentation, on the other hand, a larger number of those who favor the theory of spontaneous origin do not deny the causative influence of a specific poison. They simply assert that this specific poison may originate from causes independent of antecedent cases of the disease to which it gives rise: filth being reckoned but one among many predisposing causes.

DR. MCCOLLOM thought that disinfection when thoroughly carried out would be found a very satisfactory sanitary measure. He did not consider isolation the only thing to be done in cases of scarlet fever and diphtheria, but was a firm believer in the usefulness of disinfection. He considered that the disinfection of typhoid fever stools was a very important matter. Of the many cases of typhoid fever which occurred this last autumn, a large number of the patients were found to have contracted the disease out of the city.

He considered that the well-water in many places, especially picnic grounds, was not an uncommon source of the disease. He felt that an advance had been made when physicians were required to report cases of contagious disease. He recalled the case of a child who while returning from the country was in the railway car with a person who had diphtheria; in about five days after the child's return it became ill with the disease. As a disinfectant he recognized the value of corrosive sublimate, but he disliked to use the solution owing to its close resemblance to water. He preferred to use Labbaraque's solution or the permanganate of potassium.

In cases of small-pox, for example, isolation is not the only thing; he considered the disinfection by burning sulphur a very important sanitary measure. Although vaccination has done much to check the spread of small-pox, Dr. McCollom felt that disinfection had demonstrated its value. As showing the efficacy of disinfection, he cited the fact that no second case of small-pox had appeared in this city, after the removal of the patient and a proper disinfection of the premises had taken place.

Further, no patient, to his knowledge, had ever carried the disease out of the hospital. The clothes were hung up in a room exposed to the fumes of burning sulphur at least for twenty-four hours. At the Boston City Hospital, a few years ago, a case of small-pox appeared; this was removed and only one case, as far as he knew, ever occurred after its removal.

At the jail, a few years since, he had an experience with isolated cases of small-pox. These cases were at once removed, and disinfection of the cell and clothing was thoroughly carried out. No cases appeared afterward.

DR. C. E. VAUGHAN instanced the spread of typhoid fever in a family of seven persons, which was apparently due to the careless use of the water-closet in which the dejecta were placed.

DR. J. B. AYER said, I do not wonder that some observers feel that the theory of germ contagion does not explain *all* facts regarding contagious disease. It is, for example, hard to understand why physicians so rarely communicate disease in going from house to house.

Ten years ago I made inquiry regarding the origin of scarlet fever in my Dispensary cases and found only twenty-two per cent. traceable. At the same time I was surprised to find that numerous children escaped after exposure to the disease. I found instances where children who had kissed a scarlet-fever patient, or had slept with one, had not contracted the disease. But I am not inclined to give weight to this negative evidence, and I believe, with Dr. Durgin, that every contagious case depends upon germs from a previous case of the same disease.

I believe in the strictest isolation, and insist upon a sheet being placed outside of the sick-room door sufficiently large to cover the whole space and to allow with more safety the door to be opened at will.

I would not rely upon disinfecting fluids or powders in the room, but would recommend that this sheet be kept moistened with a strong disinfecting solution.

I do not bathe scarlet-fever patients with disinfectants, but *always use strong antiseptics in the local treatment of diphtheria.*

I believe in sulphur fumigation. Dr. Durgin has recently disinfected a children's home in this city successfully with seven hundred pounds of sulphur.

DR. HAVEN inquired if Dr. Durgin had had experience in the use of arsenic as a prophylactic in scarlet fever.

DR. DURGIN replied that he had never used it.

DR. HAVEN suggested that the objection to the colorless character of solutions of corrosive sublimate might easily be overcome by coloring the solutions with some simple coloring matter: permanganate of potassium colored the bed-linen, indigo was suggested.

DR. J. F. COUCH, of Somerville, said that it is pretty difficult to prove that there is any belief in the theory that disease is to be regarded as an evidence of the anger of the Deity. I must dissent from the view advanced by the reader, that the recent outbreak on the part of the French-Canadians in Canada was due to such a belief. A more rational explanation would seem to be that the old-time antagonism existing between the two races, the French and the English, found this method of expressing itself. My experience with the French people in the city in which I reside, leads me to believe that they have no special objection to vaccination.

I am fully in accord with the reader in his views of the contagiousness of certain diseases, and believe in the necessity of isolation and disinfection as advocated by him. Having a few years ago a special interest in this subject, I made, more particularly with regard to diphtheria, notes of the sanitary condition of the houses in which this disease occurred. My experience did not tally with the reader's, for while he found, in Boston, of the houses in which there were cases of diphtheria, only twenty-one per cent. in poor sanitary condition, I found fully ninety-seven per cent. in poor condition. I believe in the contagiousness of diphtheria, but I know of cases in which there had been no known exposure. Of the contagiousness of typhoid fever, more especially since my own unpleasant experience with that disease, I have no doubt. I am glad that the two members of the Boston Board of Health who are present express their belief in its contagiousness. A few weeks ago another member of the Board was reported in the *Sunday Herald* as saying that it

[2] See page 75.

was not contagious. Accepting the theory of contagiousness of the three diseases to which I have referred, it will be seen that to restrict the spread of these diseases it will be necessary to isolate the patient and thoroughly disinfect the premises. Except as applied to small-pox, disinfection is not in my opinion thoroughly done. Loose windows and doors not fitting snugly to their frames, require such an amount of packing to make the room air-tight, that, practically, we find the gas escaping from the room almost as fast as it is made by the burning sulphur.

There will be no material headway made against the extension of these diseases until the work of isolation and disinfection is as thoroughly applied to them, as it is in the case of small-pox, by the Boston Board of Health. Boards of health have all the power they need in dealing with such cases, and those of cities and towns adjoining each other should work together in dealing with contagious diseases.

DR. E. H. STEVENS spoke of a house where, after four fatal cases of diphtheria, the family had moved out; the paper was removed from the walls of the room, and the house was disinfected with burning sulphur. Another family moved into the house and had diphtheria.

DR. DURGIN replied to a question as to what instructions were given, to those who did the disinfections, as follows:

First. To tighten up the rooms, that is, to pack the window-frames with cotton, etc.

Second. Everything in the room should be so exposed, that the fumes of the burning sulphur should come in contact with it.

Third. Three pounds of sulphur to every one thousand cubic feet of space, is burned rapidly by the addition of alcohol.

Fourth. This is continued for six hours.

This fumigation is pursued after cases of small-pox, scarlet fever, measles, and diphtheria.

DR. STEVENS inquired regarding the treatment of the mattress, as he felt that it might be a direct source of contagion.

DR. DURGIN said that he should take off the covering, shake out the hair, and fumigate with sulphur.

DR. PAGE mentioned, in connection with, and as bearing upon the remarks of Dr. Stevens, an instance wherein a mild case of scarlatina occurred in a family with two children, in which complete separation and isolation were faithfully carried out, the other child being sent away from home. After recovery, and before the return of the well child, the room was thoroughly fumigated with sulphur, the paper on the walls removed, the room repainted and repapered, the mattress steamed, and afterwards cleansed with naphtha, the family not feeling satisfied that steaming was sufficiently protective; and yet, within three months after the second child's return, she came down with scarlatina. Assuredly, this case could not have been owing to contagion, pure and simple. It must have originated wholly from infection.

On the other hand, while a general practitioner of medicine in an adjoining State, he had often noticed in his own experience, which was large, that it was not of infrequent occurrence, in epidemics of scarlet fever, to have *one* child out of a numerous family of children, attacked with the disease, and *none of the others*, notwithstanding no attempts at disinfection, isolation, etc., were made by the family; nor were any precautions taken by them to prevent the other children from mingling freely with the sick one. While he did not wish to intimate that disinfection or quarantine were valueless, he thought that the question of the susceptibility of patients to this particular disease, which varied greatly in children, as, in fact, it does in all contagious and infectious diseases, was one which was too often overlooked. This susceptibility, or rather, want of susceptibility, was also the probable explanation why so many children escaped the disease, even after they had been exposed to it.

DR. ERNST said that he thought Dr. Durgin was mistaken in saying that the general opinion was that diseases and *disease-germs* have existed always in just the form, and with just the properties of which they are now possessed; that there is no reason for denying that an evolution of these forms may have taken place. The point to be settled is whether the pathogenic powers of a special form of micro-organism being proven, those properties can be altered by any means within our knowledge.

At this point, in reply to a question, DR. DURGIN said that he had always considered a contagious disease as "one which required an actual contact with the disease or thing." An infectious disease he considered "one that travelled through the air." He considered that the terms were used very loosely and interchangeably.

DR. ERNST said there should be a more exact use of the terms *contagion* and *infection*. It is difficult, oftentimes, to discover what the authors using the terms mean by them. Dr. Durgin's definition seemed to be the one ordinarily accepted. Dr. Durgin speaks of two classes of physicians being opposed to each other in the matter of pathogenic properties in bacteria — the one affirming, and the other denying that these lower forms of life have any power for harm in the human system. Conviction has been so widely spread among physicians, that it cannot, at present, be said that there is a *class* of medical men who deny the pathogenic powers of certain of the bacteria — *provided* that only those are considered who know something of the subject, and it is to such that Dr. Durgin refers in his paper. It is rather the *botanists* who are arrayed in opposition to the assertions of the bacteriologists.

Dr. Durgin advances the theory that certain diseases differ in their power and rapidity of transmission, because of the difference in weight of the organisms producing them. This seems to be something new, and the grounds for such a statement are unfamiliar to me. My own theory in regard to these differences in weight, which differences are, I think, too slight to permit of any differentiation, but by differences in the nature of the various bacteria themselves. For example, the bacillus of tuberculosis grows only at a certain temperature higher than is ordinarily found in the air; this temperature must be constant for some time, and there must be other conditions of moisture, nutritive soil, etc., to permit of its complete development. This explains why, with no reference to differences in weight, tuberculosis is not more evidently propagated from one case to another than it is, and why it differs from Asiatic cholera — the bacterium of which flourishes with such very great vigor at a lower temperature, and in much less time.

Dr. Durgin and some of the other gentlemen have spoken of the specific organisms of a number of diseases as if these organisms were definitely isolated and recognized. This, notably in regard to small-pox, yellow fever, typhoid, and scarlet fever. If the bacteria

of any of these diseases have been so definitely studied as to be certainly connected with the disease, it is strange that something more has not been said in regard to them. Certainly, the one who has isolated the bacterium of small-pox, should have made an effort to obtain the prizes waiting to reward efforts in that direction, and Dr. Sternberg's failure to find the specific cause of yellow fever is well known.

The report of the Committee on Disinfectants of the American Public Health Association, is a good one, and must be accepted, as far as it goes, for the present. It certainly reflects very great credit upon the members of the Committee who made it. From a scientific point of view, it is imperfect, however — as the authors themselves state — by reason of the few organisms experimented upon, and also because of the present imperfect condition of our knowledge of bacteriology. We should all be glad to know of the position of our Board of Health, and of the views which Dr. Durgin has expressed here this evening.

DR. C. P. PUTNAM inquired if fumigation with sulphur rotted cotton cloth.

DR. DURGIN said that he thought not, as a general rule, although very rarely the fumigated clothes of patients were quite tender.

DR. PUTNAM inquired if the bathing of patients with chloriated soda had any other effect than as a disinfectant.

DR. DURGIN considered that it was not unpleasant, and felt that it might aid in confining the disease to the bed. Carbolic oil was used in cases of small-pox.

DR. PUTNAM thought that chlorinated soda might make the patients sore.

DR. HAVEN suggested the use on scarlet-fever patients of corrosive sublimate soap.

DR. DURGIN, in reply to a question, stated that carbolic acid was used to wash the floors and walls of a room, and the burning sulphur to fumigate the room.

DR. J. L. HILDRETH said that he did not think that disinfection and isolation were carried far enough. He considered the law that prevented children from attending school for a specified time after recovery from the disease. He thought that the decrease of deaths that occurred in the community following the passage of this law might be explained by the subsidence of an epidemic. He mentioned some experiments which had been performed under the auspices of one of the local boards in England, which showed that the propagation of scarlet fever did not depend upon epidermal scales, and asked Dr. Durgin if he considered the desquamated epidermis as a means of spreading the disease.

DR. DURGIN replied that he knew nothing to prove that the scales were a direct source of contagion.

DR. HILDRETH inquired whether there was a definite safe period as regards contagion following a case of scarlet fever or diphtheria.

DR. DURGIN considered the two weeks' law an absurdity. He thought that when the skin was smooth after scarlet fever, danger was passed. He thought that the school law had greatly diminished the deaths from contagious diseases. The first year the mortality from scarlet fever was cut down three-quarters, and remained at a low point until 1883. The death-rate from scarlet fever at one time for a number of years, was from three to six hundred per annum, and immediately following the passage of the school law, the mortality dropped as above stated. For the last two or three years the mortality had been gradually increasing again.

DR. BUCKINGHAM said that the proposal to disinfect the skin of scarlet-fever patients by carbolized oil inunctions, is, in his opinion, dangerous, because of the rapid absorption of oil by the skin of these patients. He also said that he had seen a number of single cases of scarlet fever at various times, at the children's room of the dispensary, and, although the waiting room is often close and crowded, he had never seen any spread of the disease among the patients there in attendance. These cases had been mostly in the early part of their sickness, and he asked Dr. Ayer if, in his cases of exposure without contagion, there had been any observation as to stage. Of course his own observation was liable to the fallacies attending such inquiries in an out-patient room. He further inquired regarding the process of preparing patients for discharge from the small-pox hospital.

DR. MCCOLLOM said that the patients had six to eight baths, with a little carbolic in the water, previous to leaving the hospital.

DR. DURGIN closed the discussion, and said that he was a firm believer in the efficacy of the disinfecting of stools of typhoid-fever patients.

In answer to Dr. Couch he said that the Board of Health had always been in the habit of using large quantities of disinfectants in vaults, cesspools, and other foul places. Formerly sulphate of iron was used, but for the last two years we have used corrosive sublimate, which is much more powerful as an antiseptic and germicide. Although we might not suspect the presence of a disease germ, the use of these disinfectants is still called for to prevent decomposition, putrefaction, and foul odors.

He said that regarding the germ of small-pox and typhoid fever, he had considered that it existed by analogy. He continued: Dr. Ernst must have misunderstood me in regard to the discovery of the germs of small-pox and scarlet fever. I said I should be equally pleased with himself to learn that these germs had already been demonstrated.

The speaker felt that in speaking of germs, one naturally spoke of them as lighter than one another, for we know that the contrast in the contagiousness of certain diseases is very great; for instance, it is an established fact that in a yellow-fever epidemic, those who reside in the lower floors of a dwelling-house are particularly apt to contract the disease, while those who live in the upper stories are usually exempt from an attack. He fully accepted that the weight of a germ was not demonstrable, but considered that it was an instinctive way of speaking.

He felt that the susceptibility of the individual was a large factor in determining an attack of any contagious disease, particularly scarlet fever. Regarding the thoroughness of disinfection, he instanced a house on Charles Street, near the river, where several died with scarlet fever. The rest of the children were sent away. The house was thought to be thoroughly disinfected. On the return of the children, after a considerable lapse of time, scarlet fever again appeared. This was repeated twice in the cases of other children who moved into the house. He thought that the soil through a broken drain might become infected, and not reached by an ordinary disinfection. He did not consider that an example like this detracted materially from the advantages of disinfectants.

He did not believe in destroying the clothing of patients, or any article of value, but considered that efficient disinfection can be made sufficient.

In regard to the unsanitary condition of houses, and the comparison of the statistics of Somerville and Boston, he said that Dr. Couch had misunderstood his figures, for on investigation, only twenty-one per cent. of the houses were found in a *sanitary* condition, thus leaving seventy-nine per cent. in an *unsanitary* condition. This makes the comparison between the investigations not so unlike.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

W. E. HUGHES, M.D., RECORDER.

STATED Meeting, January 14th, 1886, the President, J. C. WILSON, M.D., in the Chair.

DR. T. S. K. MORTON presented a cancer of the lower third of the œsophagus, with metastases to the stomach and liver, from a woman, aged sixty-one years, of good family history. Her illness commenced, by her account, eleven weeks before her death, with jaundice, vomiting, constipation, and lancinating pain in the right hypochondrium. The vomiting became uncontrollable, the matters several times containing coffee-ground material. After death, there was found a scirrhus cancer of the lower third of the œsophagus, extending to the stomach, with no narrowing of the œsophageal lumen. The retro-peritoneal glands were involved, and the head of the pancreas slightly. Scattered through the liver and stomach, were numerous secondary nodules.

Also cirrhosis of the liver, with perihepatitis, removed from the body of a woman, aged forty years, who had been an excessive consumer of strong spirits. Symptoms had been present for five years, the most prominent of which were general œdema, with marked ascites and diminution of the area of liver dulness. She died of an intercurrent attack of facial erysipelas. The liver weighed thirty-six ounces, and was strongly adherent to neighboring structures. At its entrance into the liver, the portal vein was much contracted, and below this point, dilated.

Also, amyloid degeneration following chronic dysentery. The patient, a girl, aged twenty years, had no history of syphilis; there was a perfectly good family history. She had been in poor health, but with no positive symptoms, for two years. Last summer, she had whooping-cough. After that, she improved steadily till three weeks before her death, when profuse diarrhœa, with high fever, set in. This was the first attack of looseness of the bowels she had had. Jaundice gradually developed. The liver was found to be enlarged. The urine contained albumen and casts. The diarrhœa persisted, the passages containing blood and pus. At the autopsy, the liver, spleen, and kidneys were found infiltrated with amyloid material, and the large intestine was, throughout, in a state of chronic dysenteric ulceration. Dr. James Tyson said this was the first case he had ever met with in which there was this association of amyloid disease with dysentery, as the etiological factor, although this seems the only possible cause in this instance, where the possibility of syphilitic disease seems excluded.

DR. W. OSLER thought it was well recognized that chronic dysentery might be followed by extensive amyloid disease. He had met with one or two instances in connection with chronic diarrhœa, which post-mortem examination showed dependent on chronic dysentery, with very much the condition of bowel present in Dr. Morton's specimen.

Dr. Osler presented a spindle-celled sarcoma of the retro-peritoneum, with extensive thrombotic degeneration, and gave a history of the case. A man, aged sixty years, was admitted to the University Hospital in September, 1884, with an abdominal tumor, which had been noticed for about six months. He had lost flesh and strength, but there was no pain. The tumor formed a solid mass, occupying a median position, extending above the umbilicus; could be readily separated by palpation from spleen and liver. The case was regarded as one of Lobstein's retro-peritoneal sarcoma. For several weeks, the patient passed daily, over seven pints of clear urine of low specific gravity, without sugar or albumen. The patient was subsequently admitted to St. Mary's Hospital, under Dr. O'Hara, and while there, Dr. Mears aspirated the tumor, the upper part of which had become soft, and drew off nearly two quarts of bloody serum. At the autopsy, the tumor was found to occupy a central position, was covered by peritoneum, and was attached to the tissues in front of the symphysis pubis, and seemed to have grown from the subperitoneal connective tissue in this region. The upper part of the mass was represented by a soft, fluctuating cyst, containing blood and shreds of firm thrombi; the greater part formed a solid mass, which, on section, presented a brownish-red color, was firm, dry, and had all the appearance of an old unstratified thrombus. In an area, at least, 7 x 8 inches, this remarkable condition existed. At the lower part, there were two or three grayish-white masses, evidently of a sarcomatous nature. The capsule was formed of condensed fibrous tissue, beneath which, in many places, were recent extravasations.

The weight was estimated as, at least, eight pounds. The lymphatic glands were not enlarged. The kidneys were fibroid. The liver presented several secondary masses, one the size of an orange. Microscopic examination showed the primary and secondary masses to consist of closely-packed spindle-cells. The reporter drew attention to the rarity with which spindle-celled sarcoma forms a large abdominal tumor, and to the unusual site of origin. The most interesting feature was the remarkable transformation which the greater part of the mass had undergone. This was attributed to repeated hæmorrhages, and the gradual conversion of the extravasated blood into a dry, hard thrombus. Such a thrombotic change in a tumor was most unusual, and he had not been able to find reference to a similar instance. A third point referred to was the polyuria, which was, doubtless, due to irritation by pressure on the renal nerves; and lastly, a reference was made to the facility with which the growth might have been removed.

DR. J. E. MEARS thought the growth could have been removed, though the removal would have been attended with some hæmorrhage.

DR. TYSON would like to ask Dr. Osler what, in his opinion, was the effect of thrombotic degeneration on the histological elements of tumors; and again, is it possible for clots to be converted into the tissue of the original tumor, as is asserted by some?

The PRESIDENT remarked that the case was of much interest from a clinical standpoint, in view of the possibility of surgical interference, and asked Dr. Osler

whether the conditions, as found *post-mortem*, suggested any means by which such a tumor as this could be diagnosticated from a similar growth, occupying the more usual position in the lumbar region.

DR. TYSON, in connection with the clinical history, called attention to a retro-peritoneal sarcoma, presented by him to the Society last winter, which had been mistaken by him and others, for a tumor of the kidney.

DR. OSLER, in reply to Dr. Tyson's first question, stated that the only remnants of sarcomatous tissue were two or three small, but very distinct, portions in the lower attached part of the tumor; the remainder had wholly undergone this thrombotic change, and in the upper part, had become converted into a blood-cyst. This change was, no doubt, slow, with first, a destruction of the sarcomatous elements by the blood-clot, and then a slow process of necrosis. There was no evidence, in any part of the tumor, of an invasion of the coagulum by the sarcomatous elements, as is not infrequent in thrombi in other regions, as he had seen in the portal and renal veins. The chief interest in the specimen lies in the remarkable extent of the thrombotic change. Looking at the clinical aspect, he had diagnosticated the case as one of retro-peritoneal sarcoma, from its large size, its being so centrally placed, its slight movability, its distinct separation from liver, kidney, and spleen, not being placed more on one side than on the other, and from the fact that palpation in the lumbar regions gave no pain, or other evidence of kidney lesion. It was firmer above the brim of the pelvis than any other tumor he had ever examined. One remarkable feature about these tumors is their painless character; this man complained of no pain, and in two other similar growths which he described at length, pain was not a symptom.

Recent Literature.

Elements of Inorganic Chemistry, Descriptive and Qualitative. By JAMES H. SHEPARD, Instructor in Chemistry, Ypsilanti High School. Boston: D. C. Heath & Co. 1885.

This is an excellent elementary treatise, particularly well adapted for use in high and preparatory schools. The book is written with special reference to the method of instruction recommended by the author, which contemplates, in addition to didactic instruction by the teacher, a considerable amount of experimental work by the student. A scheme of qualitative analysis is included.

A Treatise on Practical Chemistry and Qualitative Inorganic Analysis. By FRANK CLOWES, D. Sc., London, Professor of Chemistry at the University College, Nottingham. With illustrations. Third American, from the fourth English edition. Philadelphia: Lea Brothers & Co. 1885.

The adoption of this book in America, and the demand for a third American edition, justifies the favorable opinion which we have previously expressed concerning it. In the present edition, the original plan of the book has been maintained, but it has been carefully revised, and, in parts, rewritten, and some additions have been made. We recommend this work as an excellent laboratory guide and text-book.

Medical and Surgical Journal.

THURSDAY, JANUARY 28, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE APPOINTMENT OF SURGEONS IN THE MARINE HOSPITAL SERVICE.

THE Annual Report of the Supervising Surgeon-General of the Marine Hospital Service for the fiscal year 1885 contains, as always, various matters of interest, and refers to one subject that is of national importance. Although the service has often demonstrated its usefulness, Congress has never made suitable provision for the appointment of medical officers. Bills to this effect have been repeatedly introduced and favorably reported by committees, but have never yet been reached for consideration, and the examination and appointment of medical officers is still a matter of regulation only.

The important duties which are entrusted to the surgeons of the Marine Service make it more and more important that a select class of men should be attracted to the corps, and it is difficult to imagine that any one would seriously urge the appointing power to cause the setting aside of regulations so obviously in the interest of humanity as those that require an examination for admission to the medical staff, simply to obtain a place for a friend, however needy, but experience has shown that nothing short of law will prevent such attempts with each recurring change of administration. Dr. Hamilton firmly believes, and we trust not without reason, that the merit system will ultimately prevail, and become firmly established.

It is hardly necessary to recall the fact that this service is not occupied alone with the health of the sailors of the merchant marine, but that in addition to other duties, the quarantine service of the United States continues, as for the past three years, under the management of this bureau. Additional interest is given to its operations by reason of the extensive epidemic of cholera which has appeared in Spain, and reappeared in its old haunt in the south of France.

This service consists, first, in a foreign inspection service; second, in the home quarantines; and third, the inspection, when circumstances render it necessary, of trains coming from Mexico and Canada, the former as protective against yellow-fever, and the latter as against small-pox. The duties of the inspectors in

foreign ports are to make a personal inspection of vessels bound to the United States, the emigrants intending to sail thereon, and their baggage and personal effects. The second and third divisions of the service are carried out by the medical officers of the service.

Whatever value one may attach to quarantine service, it is necessary that it should be entrusted to men of zeal and intelligence. In this way only can its best results be obtained, and it is little to ask of Congress that the bureau of which so much is required, should be strengthened by such enactments as shall secure the faithful enforcement of such regulations in regard to examination of candidates as already exist, that the present high character of the service be maintained, and proper inducements be held out to its medical officers to make the service their life-long occupation.

THE THERAPEUTIC INUTILITY OF CALCIC PHOSPHATES.

Recent experiments tend to throw doubt as to whether phosphate of lime, given for medical effect, is ever assimilated by the organism.

Heiden, of Pommeritz, experimented with twelve guinea pigs, all of the same litter; four were vigorous, four less strong, and four were very feeble. These were divided into sets, four in each: two strong guinea pigs being associated with two weak ones. To one strong and one weak one was given phosphate of lime mixed with the ordinary food; to the other two pigs of the set only food was given. The experimentation lasted forty-three days, and the sole result obtained appeared to be augmentation of calcic phosphate in the excrements.

Heiden concludes from these experiments that phosphate of lime is not assimilated.

The same conclusions result from the researches of other German observers. Weiske has shown that phosphate of lime added to the feed of milch cows, not only is not assimilated, but is not even eliminated in the milk. Sanson, professor of the school at Grignon, has repeated these experiments and arrived at the same conclusions, namely: that phosphate of lime, added to the daily rations of animals, is not appropriated, and all passes out in the fæcal matters and in the urine.

THE SLOANE MATERNITY HOSPITAL.

One of the daughters of the late Mr. Vanderbilt, Mrs. William D. Sloane, has announced her intention to erect and endow, in connection with her husband, a maternity hospital, to belong to the College of Physicians and Surgeons. It will be a building of brick and terra cotta, three stories in height, and one hundred feet long by seventy-five feet wide. With this building, will be presented to the trustees of the College a sufficient sum of money to furnish the necessary income to completely support it as an absolutely free institution. Exactly what will be the amount required for this purpose cannot yet be determined. It is to be known as the "Sloane Maternity Hospital," and will be erected immediately; its position being just west of the college buildings now in course of erection.

The college, through Mr. Vanderbilt's liberality, owns twenty-nine building lots, but ten of which are occupied by the college proper. Four others, at the corner of Tenth Avenue and 59th Street will furnish ample room for the Maternity, which is designed for twenty-five beds, and the plans for which are now being prepared by the architect of the college building.

Although this hospital will be under the control of the Faculty of the College of Physicians and Surgeons its business management will be in charge of a separate board of managers, consisting of five members, of which the president of the college is the chairman *ex officio*. The four gentlemen selected for the first board are William D. Sloane, representing the donors; Cornelius Vanderbilt, representing the board of trustees of the college; and Professors J. W. McLane and Francis Delafield, representing the Faculty.

A FATAL ERROR IN DIAGNOSIS.

The principal surgeons of the Hospital St. Spiridon, of Jassy, a city of Moldavia — Drs. Russ, surgeon-in-chief, and Scali, assistant-surgeon — lately committed the unpardonable blunder of mistaking a case of seven-month's pregnancy for one of cysto-sarcoma of the right broad ligament. An operation was undertaken for the removal of the supposed tumor, when a well-developed fœtus was found of the age before stated, and which lived several hours.

The details of this shocking affair are given in the *Gazetta Medicala Jassy*, a journal edited by members of the hospital staff. The mother died on the eighth day after the operation. The surgeons concerned in this case were condemned by the Superior Sanitary Council, with the recommendation to the proper authorities that their licenses be revoked. They, however, appealed to the Courts, and, after a hearing, were acquitted.

MEDICAL NOTES.

— It was announced in recent dispatches from Paris that "Sullivan and Jacques of Boston arrived here to-day to submit themselves to M. Pasteur's treatment for the prevention of hydrophobia. M. Pasteur refuses to inoculate Sullivan, as seventy days have elapsed since he was bitten." Jacques is Mr. Charles Jacobs, a native of Groton, where he still resides on the old farm of Oliver Prescott, Jr. Sullivan is John J. Sullivan, Mr. Jacob's hired man. In the first part of November last, a pet shepherd dog belonging to Mr. Jacobs was taken sick, and died in a few days, during which time the animal had licked an eruption on Sullivan's chin. A horse died shortly after, and, as

some of the animal's saliva had fallen upon abrasions on Mr. Jacob's hand, he determined, although there was no evidence of hydrophobia in either dog or horse, to make assurance doubly sure, and go to Paris for treatment at the hands of the French scientist.

— It is suggested that oil of peppermint is very useful for burns. The oil is painted on the affected part with a camel's hair brush, and the pain is said to be immediately relieved.— *Therapeutic Gazette*, 15th September, 1885.

— The prize of 8,000 francs, offered by the Belgian Academy of Medicine for an elucidation by clinical facts of the pathogenesis and treatment of diseases of the nervous centres, and principally of epilepsy, has not been awarded; but a sum of 500 francs is offered, by way of encouragement, to the author of the essay bearing the motto, "Traditionem pondero, doctrinam respicio, sequor veritatem," on condition that he allow his essay to be printed in an abridged form, with the criticisms of the Commission.

— Professor Chiara has, we learn from the *London Medical Record*, given antipyrin in various pregnant women, and his conclusions are these: 1. Antipyrin in therapeutic doses has no appreciable action on the uterus. 2. Pregnancy does not modify the action of antipyrin. 3. When it is indicated to combat fever arising during gestation, antipyrin may be administered without fear. 4. Antipyrin favors the continuance of pregnancy by subduing the fever, as do other antipyretics.

— Baudet published, some time ago, a study of three cases of nephritis occurring in the same family, from which he was led to the belief that Bright's disease might, in certain cases, be hereditary. This hypothesis has received a certain measure of confirmation from another series of cases published by Kidd (*Ann. de la Société de Med. d'Anvers*, 1885), in which, out of the twelve children of a female suffering from Bright's disease, seven died of the same malady.— *Florida Medical and Surgical Journal, December*, 1885.

— *The Los Angeles Times* gives the following statistics of the climate of Santa Anna Valley, which will be found interesting to the health-seeker: Out of 365 days there were 332 pleasant days in 1880, 323 in 1881, 342 in 1882. For these three years the average temperature was 65°, 65¼° and 65½°. The average temperature for each month of 1885 ranged between 58½° and 73½°. The average velocity of the wind is about four miles an hour.

— Says the *Sanitary News*, of Chicago: "A Committee from the Massachusetts Medical Society, consisting of six physicians, has been appointed to urge upon the Legislature the advisability of the reorganization of the State Board of Health, by separating it from the Board of Lunacy and Charity. It was an act of lunacy to consolidate these three Boards in the first place, and it will be an act of charity to separate them again."

— Dr. H. P. Walcott, of Cambridge, has been in Washington during the past week, in his capacity of President of the Public Health Association. He is trying to unite the National Board of Health and the various State Boards, in support of a bill to establish a National Commission, to be made up of representatives from the various State Boards. We understand that a bill is in preparation with this in view, and that all the health associations will probably unite to urge its passage.

— In a supposed murder case in Detroit, the county physician testified that the victim, a woman, was killed by a blow on the head. Her two sons were placed under arrest. After the examination, the skull was brought to the city and examined by four physicians, who declared that death resulted from pneumonia, and that the fractures which the county physician found, were produced by himself in removing the top of the head to examine the brain. The two sons have accordingly been released.

— The digestibility of cheese depends a good deal, according to Klenze, on its physical properties. All fat cheeses are dissolved or digested with great rapidity, because the molecules of casein are separated only by the fat, and so the solvent juice can attack a large surface of the cheese at one time. Whether the cheese be hard or soft does not appear to matter, and there is no connection between the digestibility and the percentage of water present in the cheese. The degree of ripeness and the amount of fat have, however, considerable influence, for both these conditions render the cheese more friable, and so allow of intimate contact of the juice. Cheddar took the shortest time to digest (four hours), whilst unripe Swiss cheese required ten hours for solution. — *Lancet.*

— Dogs doomed to die in London do not suffer half so much as men who pay the extreme penalty. The unclaimed curs trot into the lethal chamber at Battersea, which is filled with narcotic vapor, produced by passing carbonic oxide over a surface of anæsthetic mixture, composed of chloroform and bisulphate of carbon. Àpropos of this provision a correspondent of the *St. James's Gazette* says: "Perhaps some of those who read in one of the newspapers of the quick, painless and peaceful death suffered by the unclaimed dogs at Battersea may have been struck, as I was, with the thought that the criminals who are condemned by our law to suffer death are treated worse than the dogs. At Battersea, where the arrangements were planned under the supervision of Dr. Richardson, the dogs who are condemned to death are 'wheeled into the chamber, they lie down, curl themselves round, fall asleep, and so their lives are closed.' Surely such an ending for a murderer would not only be more humane, but would be more solemn and impressive than some of the scenes which are reported from time to time in connection with the present system of hanging."

— Our English contemporaries are calling attention to a number of recent deaths of ladies at the toilet through the catching fire of light evening dresses, owing to the inflammable material of which they are made

coming in contact with a candle or gas flame. It suggests as a precaution that muslins and such light fabrics be steeped in a solution of sodium tungstate, which will render them non-inflammable, so that they may safely be worn in dangerous situations. Tungstate of soda is comparatively inexpensive, and, by the outlay of a couple of shillings, the dresses of the whole household may be protected from fire. To three parts of good dry starch, add one part of tungstate of soda, and use the starch in the ordinary way. Should the material not require starching, dissolve one pound of tungstate of soda in two gallons of water, well saturate the fabric, and then let it dry. It will not affect in any way even the most delicate color, and ironing does not interfere with the efficacy of the process. Muslin so treated may be held in the flame of a candle or gas lamp without catching fire, so that, although the part in contact with the flame may be charred, or even destroyed, there is no danger of its spreading.

— A correspondent writes to the *British Medical Journal*, that while the late Dr. W. B. Carpenter lost his life from an accident whilst taking a lamp-bath, yet that valuable remedy (of whose efficacy he was well aware), is in no way to be discredited in consequence of the accident. It would appear that an open gallipot was used to hold the spirits of wine, and that this was upset when he endeavored to rise from the chair. Those who are accustomed to administer such baths, use tin lamps with a broad base, which are difficult to upset, and are, moreover, provided with a wick and cover, and some with hot-water vessels placed over the lamps. The writer recommends, as the best contrivance for this purpose, the Malvern lamp (invented by the late Dr. J. M. Gully and Mr. Hamsher, of Great Malvern). It is made like a school-inkstand, with a movable top, which is removed when the spirit of wine, or methylated spirit, is poured in, and which subsequently serves to regulate the height of the flame. The hot-water vessel will be found unnecessary, as a can of hot water left open and placed between the feet, will answer all practical purposes, thus preventing congestion of the head, and shortening the process by its contribution of warm vapor. The extinguisher should be placed on the lamp by an attendant before the patient attempts to rise.

NEW YORK.

— Dr. Cyrus Edson, Chief of the Second Sanitary Division, has seized between six hundred and seven hundred oranges, recently received from Florida. It seems that they were frozen on the trees during the cold weather of the early part of January, and in consequence, have become unfit for eating.

— At the annual meeting of the Hospital Saturday and Sunday Association, held recently at St. Luke's Hospital, it was reported that $40,407 had, thus far, been received from the collections and gifts to the fund during the year. Other contributions to be sent in, it was announced, would increase the amount to $46,000, and it was hoped that the effect of an appeal recently sent out to a number of corporations, would bring it up to $50,000. The increased amount this year, as compared with last, has been mainly due to the larger collections in the churches. Last year, the hospitals received, after the expenses of the collection had been deducted, the sum of $29,917.

PHILADELPHIA.

— The Mutual Aid Association of the Philadelphia County Medical Society, instituted in May 1878, has now accumulated sufficient funds to enable it to enter upon its benevolent work, and to devote a part of its income to the purposes of its organization, which was principally to assist the families of deceased members where such assistance is urgently needed. This is the first time in its history when it has been able to respond to such calls, because its capital has not hitherto reached the minimum limit established by the by-laws, but it has been enabled to do some charitable work. It is capable of doing very much good, as we know from the history of the New York Society from which it derived its inspiration.

— The recent action of the County Medical Society with regard to the delegates to the American Medical Association, and the passage of the resolution urging a restoration of the *status quo* for the sake of "the promotion of professional harmony," has had quite the opposite effect at home, whatever may be the chances of its ultimate success at St. Louis, of which many entertain grave doubts. The election of the delegates has been contested on the ground that the election was irregular and opposed to the by-laws, which require that the nominations shall be made at the preceding stated meeting. This controversy will serve to infuse new life into the proceedings of the Society for some time to come, and will indirectly be of service in increasing the attendance upon the meetings, and therefore if an evil, it will not be an unmixed one. If all the members could be made to attend and vote, at the next quarterly meeting, it is not improbable that the action of the last meeting would be reversed, and the harmonious advocates of the original committee might find themselves left in the minority.

— At the Pennsylvania Hospital recently, during Dr. Da Costa's clinic, a case was shown which possessed unusual features, and illustrated the effects of a new remedy. A boy, eleven years of age, had been brought into the wards a short time before, suffering with chorea to such an extreme degree that he was completely helpless; he had no power to walk, could not feed himself, and could not even articulate words with sufficient distinctness to make his wants known. The muscular movements did not cease entirely at night. He was given hyoscyamine in doses of 1-200 grain, which was soon increased to 1-100 of a grain given three time a day. This remedy had been used in tremor with such marked effect as to lead the lecturer to give it a trial in chorea. The effect was very marked. In four days the boy was out of bed, and going about the ward, and he had steadily improved since. When shown, nearly three weeks after admis-

sion, the muscles were quite steady and the boy could walk naturally, and he was ready to go home.[1]

— Dr. H. C. Wood exhibited an interesting case at the meeting of the County Society held on the 20th inst. It was that of a young man, about twenty-five years of age, who presented the following interesting group of symptoms: hemiplegia and hemianæsthesia of the right side of his body, including the face; vertical hemiopia (the right half of the field of vision of the left eye was deficient; the right eye had been lost), decided diminution of hearing in the right ear, and persistent aphasia. In order to account for the symptoms, Dr. Wood inclined to the hypothesis of a double lesion, in the left hemisphere of the brain, one in the course of the motor tract in the internal capsule encroaching upon the optic thalamus, the other in the vicinity of the third frontal convolution, and especially involving the claustrum. The history of the case, unfortunately, was defective. The lecturer regarded a multiple lesion as an evidence of syphilis. At the same meeting Dr. Bruen presented a case of supposed syphilitic disease of the lung, which had improved under treatment, and Dr. J. H. Musser showed sections of a case of syphiloma of the lung, where both lungs were found invaded by numerous miliary gummatous deposits around the smaller arteries especially; there were no signs of attending inflammation of the mucous membrane, interstitial cellular tissue, or the pleural investment of the lungs; the patient died with acute meningitis, which may have been syphilitic also, as similar deposits were detected in the brain.

Miscellany.

ON A CONDITION OF THE INNER SURFACE OF THE UTERUS, AFTER THE BIRTH OF THE FŒTUS, OF PRACTICAL IMPORTANCE.

DR. J. BRAXTON HICKS read in the Section of Obstetric Medicine at the Annual Meeting of the British Medical Association in Cardiff, a note calling attention to a condition occasionally noticed after the expulsion of the fœtus; and which may easily give rise to mistakes of a clinically grave character. (*British Medical Journal*, October 10.) He says:—

When the uterus is emptied of the fœtus, the area of its inner surface is proportionally reduced. If the lining tissue also became contracted to the same extent as the muscular substance, then it would lie smooth and level; but, in some cases, this is not so; consequently, it is thrown into folds or waves, imitating in some instances, growths springing up loosely from the surface. But there is a still further state which adds much to difficulties of diagnosis, and, consequently, to danger in practice; for this inner membrane (I speak from the clinical point of view) is not unfrequently resting loosely on the muscular coat beneath, so that, when the fingers are pressed against it, it glides over the subjacent part, so as to feel very like a portion of the placenta, or the thickened membranes; so much so, that, in some cases, till I had traced it for some distance, I could not tell its exact nature. Where nodules of inflammatory deposit occur in the same case, there this portion is fixed firmly to the muscular tissue beneath, but beyond it is loose; and thus there is a great similarity to the placenta, I mean where the placenta has been already removed. The cases in which I have particularly noticed this condition, are those where I have had occasion to remove the placenta for adhesion. I have not noticed it where, for other reasons, I have passed the hand within the womb, as in ordinary turning; nor in, by any means, every case of adherent placenta. Yet, inasmuch as, in such cases, one does not specially look for such phenomena, it is impossible to say in what proportion it might exist. In the first case that I observed it, it was most marked. It was in a case to which I had been called, of very difficult labor, in consequence of miserably ignorant attempts at delivery, whereby both arms had been brought down over the back, and were drawn down outside the vulva, both humeri having been broken. The placenta was adherent, and in passing the hand to remove it, I was on the point of mistaking this loose lining of the womb for the placenta, and was about to detach it when, in passing my hand over the placenta, I concluded that it was the uterine surface covered by the smooth membranes. To make quite sure, I penetrated the placenta from the amnial surface, where I was quite sure of its presence, and worked outwards to the margin, and thus was able to safely remove it. I need not record more cases, for attention having been once directed to it, it will, I think, be readily comprehended. I am not aware of any one having noticed or pointed out the peculiarity before, though I can hardly think it could have escaped observation; but, in the excitement of the moment, the danger of mistaking the lining of the uterus for adherent placenta is undeniable, and this must be my excuse for occupying your time.

[1] This case was made the subject of a clinical lecture, which can be found in the Philadelphia Medical Times for January 23.

Correspondence.

HUMANIZED VIRUS.

BOSTON, 27 Dudley St., Jan. 25, 1886.

MR. EDITOR, — Had Dr. Chapin been familiar with the effects of long-humanized virus, he would not have written either his first or second letter. The quotation from Dr. Leonard in the latter will conclusively prove to any one who knows what vaccination was in this country sixteen years ago, and is to a great extent in Great Britain to-day, that the stock of virus used by the Health Officers of Providence certainly cannot be that of long humanization, as claimed in the first letter, but must have been modified by renewal from the cow within a comparatively few years.

Virus after one, twenty, or one hundred human removes, is "humanized virus," but that is a very different thing from virus of eighty or even thirty years' unbroken human transmission.

The picture I drew of the effects of the virus now in use by the Health Department of Providence, applied to that virus, as I distinctly stated, *if it had the pedigree claimed for it*, but that it is either an "erroneous" or "purely imaginary" picture of the effects of long-humanized virus, I utterly deny. It is based upon the careful study of a very great number of vaccinations with the stock of the National Vaccine Institution of Great Britain (preserved with religious care in a state of excellence unknown anywhere else, and which it would be folly to say was not the very best and most active stock of long-humanized virus extant)

and also upon the writings of the most eminent observers from the time of Bousquet. If Dr. Chapin will procure some authentic long-humanized virus from the institution named, and watch its effects, he will see that my description is strictly accurate. My father's Report on Animal Vaccination to the American Medical Association in 1877, in which he gives an exactly similar description, was reviewed at great length by the highest authorities and in the leading medical journals of Great Britain. In that country through ignorance of animal vaccination and through prejudice the profession are overwhelmingly in favor of long-humanized virus, and its reputation is guarded with the utmost jealousy. In not one of these reviews was the slightest exception taken upon this point, as there certainly would have been, had it been open to such. Allow me to say that I never held that vaccination with long-humanized virus was not to a greater or less extent protective from variola : but I do hold that it induces an imperfect vaccinia, and that post-vaccinal variola is far from uncommon in subjects so vaccinated. Animal virus on the other hand, produces the perfect disease, and is naturally a far surer protection.

A typical scar, and one proving the most perfect vaccinal effect, is not as was once universally taught in the schools, foveolate ; but is characterized by rays or bands of cicatrical tissue. I do not admire a "deep, *smooth* scar," and never intimated that I did. I repeat most decidedly that the Providence virus cannot be the long-humanized, though I have no doubt that Dr. Chapin honestly believes it to be such. It was to guard against just such sources of confusion and wrong deductions, that I stated in my paper that the comparison suggested was not now possible here.

Yours respectfully,

STEPHEN C. MARTIN, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 16, 1886.

Deaths reported 1,513: under five years of age 516; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases whooping-cough, erysipelas and fevers) 192, consumption 231, lung diseases 242, diphtheria and croup 95, scarlet fever 22, typhoid fever 12, whooping-cough 18, diarrhœal diseases 18, malarial fever nine, puerperal fever five, erysipelas seven, small-pox two, measles three, cerebro-spinal meningitis two. From whooping-cough, New York 13, Baltimore two, New Orleans, District of Columbia and Providence one each. From diarrhœal diseases, New York six, Providence three, Nashville, Charleston, Lynn and Fall River two each, Boston one. From malarial fever, New Orleans three, Baltimore two, New York, District of Columbia, Charleston and Springfield one each. From erysipelas, New York four, Boston, District of Columbia and Fall River one each. From puerperal fever, District of Columbia two, Nashville and New Orlean one each. From small-pox, New York two. From cerebro-spinal meningitis, Fall River and Fitchburg one each. From measles, New York one. From typhus fever, New York one.

In 108 cities and towns of Massachusetts, with a population of 1,242,372 (population of the State 1,941,465), the total death-rate for the week was 17.16 against 16.98 and 18.18 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,906,446, for the week ending January 2d the death-rate was 25.5. Deaths reported 4,360: infants under one year of age 959; acute diseases of the respiratory organs (London) 610, whooping-cough 168, measles 163, diarrhœa 49, diphtheria 41, fever 38, scarlet fever 34, small-pox (Liverpool, two, London and Bristol one each), four.

The death-rates ranged from 16.0 in Hull and 36.8 in Nottingham; Birkenhead 23.0; Birmingham 24.2; Bradford 21.7; Leeds 23.3; Leicester 21.5; Liverpool 27.9; London 26.5; Manchester 29.5; Newcastle-on-Tyne 23.5; Sheffield 18.4; Sunderland 19.6.

In Edinburgh 19.2; Glasgow 23.3; Dublin 37.1.

For the week ending January 2d in the Swiss towns, there were 20 deaths from consumption, lung diseases 24, diarrhœal diseases nine, diphtheria and croup six, small-pox and whooping-cough each four, typhoid fever one.

The death-rates were: at Geneva 10.1; Zurich 13.6; Basle 12.9; Berne 25.1.

The meteorological record for week ending January 16, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Jan. 16, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE TWO WEEKS ENDING JANUARY 16, 1886.

SAWTELLE, H. W., surgeon. To proceed to Los Angeles and Wilmington, Cal., as inspector, January, 1886.

GODFREY, JOHN, surgeon. To proceed to Chattanooga, Tenn., and Rome, Georgia, as inspector, January 8, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 16, 1886, TO JANUARY 22, 1886.

WEBSTER, WARREN, major and surgeon. Sick leave of absence further extended nine months on account of sickness. S. O. 15, A. G. O., January 19, 1886.

APPOINTMENTS.

By the overseers of Harvard College in concurrence with the President and Fellows: Edward Lawrence Mark, Ph.D., to be Hersey Professor of Anatomy. William Lambert Richardson, M.D., to be Professor of Obstetrics.

RESOLUTIONS ON THE DEATH OF DR. JAMES H. WHITTEMORE.

At a meeting of the Boston Medico-Psychological Society held on the evening of January 21st, the following resolutions were unanimously adopted:

Resolved, That in the death of Dr. James H. Whittemore the Society has lost a friend who was one of the most active and valued of its original members, whose frankness, charm of manner, and unselfishness endeared him to all.

Resolved, That the Society desires to express its personal grief, its appreciation of his patient courage in suffering, and its sympathy with his family in their bereavement.

Resolved, That the Secretary be instructed to send a copy of these resolutions to the family of the deceased, and cause the same to be published in the *Boston Medical and Surgical Journal*.

J. B. AYER, M.D.,
F. M. TURNBULL, M.D.,
P. C. KNAPP, M.D.,
Committee for the Society.

RESOLUTIONS OF THE BOSTON TRAINING SCHOOL FOR NURSES IN MEMORY OF DR. J. H. WHITTEMORE.

The directors of the Boston Training School for Nurses, deeply sensible of the loss suffered by the community in the recent decease of Dr. Whittemore, desire to give expression to their own great sense of loss in his too early death. Brought into close contact with him in all the details of working a training school for nurses, they ever found him ready to help and forward their work, while his liberality and openness of mind and constant, cheerful co-operation, have had much to do with the present position and activity of the school. The welfare of the nurses was always an object of his closest interest, and the admirable building in which they now live is the result of his energy and care, aided by a most liberal giver to the hospital The nurses will long miss his cheery presence among them, as well as his wise assistance.

The directors themselves, in carrying out their work, owe much to his consideration and courtesy; and their sense of loss and of admiration for his character and heroic endurance is deep and abiding.

To his family they would offer their deepest sympathy.

For the Board, CHARLES P. CURTIS.
ELLEN T. VAUGHAN.

RESOLUTIONS OF PLYMOUTH DISTRICT MEDICAL SOCIETY ON THE DEATH OF W. P. BROWNELL, M.D.

BROCKTON, January 22, 1886.

MR. EDITOR, — In accordance with a vote of the Plymouth District Medical Society held at Brockton, Wednesday, January 20, 1886, I send the following:

Whereas, Dr. Nathan P. Brownell of South Scituate, a worthy member of this Society, died at his home, December 30, 1885, and while lamenting our loss it is hereby

Resolved, that to his family in their bereavement we tender our warmest sympathy, and to the community in which he moved our sincere regret at their loss of a high-minded physician, friend and citizen.

A copy of the above resolutions was also to be sent to his wife. The Society so voting. J. E. BACON,
Secretary of Plymouth District Medical Society.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, February 1, 1886, at 8 o'clock P.M. Readers: Dr. T. M. Rotch, "Cases of Interest in Practice." Dr. J. W. Elliot, "A Case of Salpingitis with Severe Symptoms: Removal of Tubes and Ovaries: Recovery." Report of the Committee on the Circulation and Distributions of the Journals.

H. L. BURRELL, M.D., *Secretary.*

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION. — The regular meeting of the Section will be held on Wednesday evening, February 3d, at 8 o'clock. Communications: Dr. D. W. Cheever, "Chronic Obstruction from Congenital Malformation of the Bowels: Tentative Operation: Death." Dr. George W. Gay, "Laparotomy for Stricture of the Small Intestine: Death: Autopsy."

S. J. MIXTER, M.D., *Secretary.*

CORRECTION.

BOSTON, January 22, 1886.

MR. EDITOR, — In the preceding number of the JOURNAL I am reported as having said that "Da Costa has grounds for the opinion that pericarditis is not influenced by internal medicines." This should read "by salicylate of soda."

Yours very truly, F. MINOT, M.D.

BOSTON, January 23, 1886.

MR. EDITOR, — In the report of the Improvement Society in the JOURNAL of January 21st, page 61, of the discussion of Dr. Abbot's paper on Pericarditis, I am credited with saying that I had never had a fatal case. This is incorrect, for I recall two such at least. Yours truly, G. H. LYMAN.

BOOKS AND PAMPHLETS RECEIVED.

A Manual of Auscultation and Percussion. Embracing the Physical Diagnosis of Diseases of the Lungs and Heart and of Thoracic Aneurism. By Austin Flint, M.D., LL.D. Fourth Edition, Revised and Enlarged. Illustrated with fourteen woodcuts. Philadelphia: Lea Brothers & Co. 1885.

Lecture.

LECTURE ON HYPNONE.[1]

BY DR. DUJARDIN BEAUMETZ,

Physician to the Cochin Hospital, Member of Academy of Medicine, Paris, France.

At the session of the Academy of Sciences for November 9, 1885, I made known, in conjunction with Dr. Bardet, the hypnotic properties of a mixed acetone, known under the name of *aceto-phenone*, or *phenyl-methyl-acetone*, and to which I have given the name of *hypnone*.

Since this first communication, numerous experimental researches have been made on the physiological action of this body, clinical observations have multiplied, the modes of pharmaceutical administration have been perfected, so that to-day we can make an almost complete study of this acetone.

Discovered in 1857 by Friedel, aceto-phenone is the type of a numerous class of mixed acetones having for general formula, $C_{2n}H_{2n-8}O_2$, and which take their derivation from two organic acids, the one belonging to the fatty series, the other to the aromatic series, whence the name of *aromatic acetones* also given to this group of bodies.

This aceto-phenone, which has for atomic formula C_8H_8O, has different names, and if you will turn to the important work of Bourgoin,[2] you will see that it has been successively called *methyl-benzoile*, *acetylphenyle*, *acetylbenzol*, *methylphenylacetone*, *phenylmethylketone*.

For all these chemical appellations, we have deemed it best to substitute, from a practical and therapeutical standpoint, a smoother medical term, and have proposed the name of hypnone, which recalls at once the physiological properties of this body, and the chemical group to which it belongs.

Chemists embarrassed by the scientific exigencies which compel them to give to a substance which they discover names of greater and still greater complexity, seem unable to furnish smooth terms for medicinal substances, and we find the same inconveniences to which we have alluded, in the nomenclature of the new antipyretics. Hence, for the complex names of *dimethytoxyquinisine* and of *tetrahydroparamethyl oxyquinoline* have been substituted for sufficient reasons the briefer appellations, to-day accepted by every body, of *antipyrine* and of *thallin*. We have taken the same liberty with regard to aceto-phenone, for whose numerous synonyms, by the way, there seems to be little justification.

Hypnone is obtained by submitting to distillation a mixture of benzoate and acetate of calcium. It presents itself at the ordinary temperature in a liquid state, but it suffices to lower the temperature four or five degrees for this body to assume a solid crystalline state. Hypnone is a colorless, very mobile, very refractive liquid, boiling at 198°C. The specimen which served for our experimental researches had been very obligingly put to our disposition by M. de Laire. Aceto-phenone is a product of the laboratory; it has not yet been fabricated on a large scale by the arts, hence its retail price is still very high, almost two hundred francs per kilogramme. Limousin, who has studied with care the chemical and physical properties of this body, has shown that it is neither soluble in water nor in glycerine, but that it is very soluble in alcohol, ether, chloroform, benzine, and turpentine. Its density is very nearly that of water; one cubic centimetre weighs 1.6 gms. With the graduated dropping tube of Lebaigue, one cubic centimeter of hypnone gives from 39 to 40 drops. Every drop weighs about two and one-half centigrammes. The reaction of this body is neutral, but it is irritant and caustic and when applied to a mucous membrane, it provokes pain and severe smarting.

Hypnone has a very persistent odor which resembles at once that of newly-cut hay, of convallaria, and of cherry laurel water. This odor is so persistent as to render its administration in potion very difficult; however, M. Vigier, who in accordance with my request, has made a careful study of the best means of administering hypnone has proposed the two following formulæ; the one is a syrup, the other an elixir.

The whole may be thus reduced to the American style of formulating:

SYRUP OF HYPNONE.

℞ Hypnone gtt. xii,
Alcohol at 90° ℥ ii
Syrup Auratii Cort. ℥ x
M. Sig. Every teaspoonful has one drop and the dose is a teaspoonful to be repeated *pro re nata*.

ELIXIR OF HYPNONE.

℞ Hypnone gtt. xii
Alcohol at 60° } aa ℥ iii.
Syrup of Tolu }
Spts. Menth. q. s. to flavor
M. Sig. A tablespoonful when required.

PETIT'S SYRUP OF HYPNONE.

℞ Hypnone gtt. xvi
Alcohol at 90° ℥ i
Glycerine ℥ i
Simple Syrup ℥ ii
M. Sig. A tablespoonful when required. Each tablespoonful contains two drops hypnone.

All these preparations have been abandoned despite the advantages which they present, and this chiefly by reason of the great quantity of excipient in which one is obliged to dissolve the dose of hypnone necessary to provoke sleep. The only really good mode of administration is that of the capsule whether the hypnone be dissolved in oil, after the fashion of Limousin and Adrian, or whether ether be employed as the excipient, as in Clertan's pearls. These capsules contain from five to ten centigrammes of hypnone.

But before studying the therapeutical applications of aceto-phenone, we must describe its physiological and toxic properties. To our first researches on this subject, are added those of Professor Grasset of Montpellier, of Drs. Laborde, Mairet, and Combemale, and finally those of MM. Dubois and Bidot; the latter is even devoting his inaugural thesis to a complete study of hypnone. It is from the sum of these researches that we are able to-day to give a quite complete description of the physiological and toxic effects of aceto-phenone.

These physiological and toxic properties vary according to the animals which are the subjects of experimentation, and according to the mode of introduction of the hypnone. In the guinea pig, when fifty centigrammes (gr. vijss) of aceto-phenone are injected under the skin, a hypnotic torpor is engendered, which soon gives place to a comatose state, in which the animal succumbs in from four to six hours. At the autopsy, numerous sub-pleural ecchymoses are observed; the heart is arrested in diastole, and the flesh exhales the odor of aceto-phenone. When the dose is raised, the toxic phenomena are not increased; and this is ex-

[1] From advance sheets.
[2] Bourgoin. Encyclopedie Chémique, t. vii, p. 341.

plained by the irritant local action of the aceto-phenone and its little solubility from which results that whatever may be the quantity administered by the skin, it enters the economy in but feeble amount.

The hare, like the guinea pig, is sensitive to the action of hypnone, but one may without injury and without causing death, inject two gms. (ʒss) of this substance under the skin. Hypnone entails loss of sensibility in the paw where the injection is made. The temperature falls from 39.6° C. to 38° C.; the urine has the odor of hypnone, and is precipitated by nitric acid; then the animal falls into an absolute inertia, but at the end of twenty-four hours he is perfectly recovered.

This local insensibility produced by hypnone is even more noticeable when the frog is the subject of experimentation, and the paw where the injection of a few drops of hypnone is made, becomes insensible and loses its reflexes. If in the animal you dissect out in each leg the nerve which supplies the gastrocnemius, you observe that while the nerve of the paw where the injection was made has lost its sensibility to electric currents, the other nerve has kept its sensibility perfectly intact.

In the dog the symptoms are variable according to the mode of administration of the medicament; when you employ the hypodermic method, hypnone, even in the dose of three gms. (forty-five grains), does not seem to produce any hypnotic effect, and this fact has been well established by Laborde, Grasset and ourselves.

When hypnone is taken into the stomach, you see sleep supervene, on condition, however, that the irritant action of the medicament on the mucous membrane of that organ does not produce vomiting. Laborde has devised a mixture of hypnone, of glycerine and of water, which is well accepted by the dog, and which in the dose of from one to two cubic centimetres causes insensibility in the animal. We have obtained the same effect with capsules of hypnone, which we have administered to dogs, and without always producing sleep, we have obtained a well-marked state of stupor and inertia, with a dose of twenty centigrammes. But these hypnotic phenomena are much more prompt and complete, according to Grasset, when the medicament is introduced into the lungs by intra-tracheal injection: in this event you obtain profound sleep without causing the death of the animal. It is not so when you introduce the medicament by the veins, in which event the symptoms attain their highest degree of intensity, and the animal always succumbs after this injection.

When in a dog weighing seventeen kilograms (about thirty-five pounds) you make an intra-venous injection of one cubic centimetre of hypnone, you produce a profound sleep with snoring; the analgesia and anæsthesia are complete, and there ensue marked modifications in the respiratory and cardiac functions. These modifications are chiefly characterized by a considerable depression of the arterial tension. The respiration becomes interrupted and irregular. At the end of a certain time the animal wakes, manifests incoördination and intoxication, and succumbs after from six to ten hours. At the necropsy you find appoplectiform lesions, with abundant sanguineous infiltration of the lungs, of the liver, and of the kidneys. The renal congestion is very marked, and causes sanguineous extravasations in the urine. It is worth remarking in this connection, that Grasset has obtained no hypnotic effect in the monkey with aceto-phenone.

To sum up; according to the foregoing experiments in animals, hypnone seems to have a triple action: (1) on the nervous elements, diminishing neurility; (2) on the blood pressure, which it lowers; (3) on the composition of the blood, which in toxic dose it modifies. It is to this triple action that it owes its hypnotic properties. In a clinical lecture which I have lately given on the "New Hypnotics," I have shown that in order that a medicament may be classed in this group it must lessen the cerebral circulation and the excitability of the nervous elements, and in his recent thesis Dr. Pinard has also laid down this principle. Hypnone having thus double physiological action, ought to be classed among the true hypnotics.[3]

Aceto-phenone is eliminated by the lungs and by the urine. It is worthy of note that an article which appeared prior to our communication to the Academy, Popof of Vorsovia and Meneki had asserted that aceto-phenone is transformed in the organism into carbonic and benzoic acid and is finally eliminated in the state of hippurate.

Aceto-phenone, moreover, is toxic, but it will not do unduly to exaggerate this noxious action. In animals this medicament is given in toxic, and not in therapeutic dose, and the very interesting results obtained by Laborde from intravenous injections do not absolutely correspond to what takes place when the medicament is given by the mouth.

When you introduce directly in massive dose into the blood a medicine which is but slightly soluble, and which is irritant, you modify unfavorably the conditions of experimentation with the medicament, and we may compare what takes place with aceto-phenone, with the results obtained with intravenous injections of chloral, a method once proposed by Oré, of Bordeaux, for obtaining surgical anæsthesia, but which has been abandoned by reason of the dangers which attend it. In these cases of intravenous injections of chloral, you get anæsthesia, it is true, but you also get hæmaturia and sub-pleural ecchymoses.

Moreover, as we shall shortly see, the only consequences following the introduction of hypnone into the human subject have been sleep. Even when in the same patient we have prolonged the doses for months, we have never seen any of those effects of denutrition which Mairet and Combemale have noticed in their animals; it is true that we have never exceeded the dose of fifty centigrammes. To finish what we have to say about the toxic action of hypnone, it would seem that the greater or less purity of this substance plays an important part in the production of these toxic phenomena. Experiments made in the physiological laboratory of the Faculty seemed to have settled this question.

These are the symptoms which are observed in a healthy man after the administration of twenty centigrammes (three and one-third grains) of hypnone. In the case of the ether-hypnone capsules, at the moment of the rupture of the capsule in the stomach, there is a sensation of heat followed by a few eructations having the penetrating odor of aceto-phenone; these symptoms are scarcely noticed when the capsules contain a mixture of hypnone and oil. Then, at the end of a time which may vary from twenty minutes to three-quarters of an hour and even an hour, the eyes close and sleep ensues. This sleep is ordinarily calm and it is quite

[3] Dujardin Beaumetz in Therapeutic Gazette, December, 1885. Pinard, On Sleep and on Medicaments properly called Hypnotics.—Thèse de Paris, 1885.

deep; waking is generally easy, without that nausea and loss of appetite which so often attend chloral and paraldehyde. In other cases, however, headache is felt, that heaviness of the head, and that pain over the eyebrows which are so often observed after a drugged sleep. We have never observed any other modification in the economy; the absence of any chemical reagent has never enabled us to detect the presence of aceto-phenone in the urine. The blood examined by the spectroscope has presented no alteration; the respiration and circulation go on as in the normal state. At the same time, we have remarked in certain cases a notable increase of appetite, due, perhaps, to the local irritant action of the medicine.

The hypnotic effects of hypnone are far from being constant, and you will see persons absolutely rebellious to this agent which seems rather to favor sleep than provoke it, being neither analgesic nor anæsthetic in doses of from twenty to forty centigrammes. Nevertheless — and this is an interesting point — its hypnotic action, according to Debois and Bidot, notably augments the anæsthetic effects of chloroform. These experimenters have shown that when you cause a dog to inhale a four per cent. mixture of chloroform, you do not produce anæsthesia, but if previously you take care to inject under the skin one cubic centimetre of hypnone, you then produce anæsthesia as profound as with a twelve per cent. mixture, and when the animal awakes, if you administer to it another cubic centimetre of hypnone, it falls asleep again. According to Dubois and Bidot, hypnone proves itself far superior in these cases to morphine. New researches are being made by these experimenters to ascertain if anæsthesia may not be produced by inhalations of a mixture of chloroform and hypnone. Aceto-hypnone also augments in a marked manner the hypnotic and anæsthetic action of chloral.

As for the therapeutic applications of hypnone, they have consisted almost exclusively in the treatment of insomnia; but insomnia is a symptom of complex origin, and it is necessary here carefully to discriminate the cases.

Having a very feeble analgesic power, hypnone does not seem to act in cases of insomnia caused by the persistence of pain, and in this respect this medicament has proved itself very inferior to chloral. It is the same when the absence of sleep is due to persistency of coughing, as in the phthisical, and we have had no well-marked results from it in such cases. When, moreover, the insomnia results from the febrile state, hypnone has little action, and is inferior to chloral and paraldehyde. But it is not so when we have to do with nervous insomnia, or with that sleeplessness which is produced by cerebral excitation, whether resulting from alcoholic excesses or from mental strain. Here hypnone is equal and even superior to the other hypnotics, and the observations of Huchard, as well as those of Labbé, are absolutely confirmative of those which we have obtained. In these cases aceto-phenone, in the dose of twenty to forty centigrammes, produces a calm sleep, without nightmare, followed by a tranquil awakening, and freedom from that nauseous state which other hypnotics so often determine. But, in order that hypnone may produce its hypnotic effects, it is essential that the patient shall not have been an habitual morphine taker. In morpiomaniacs it fails, as do most of the other hypnotics.

Hypnone has been administered by mouth, and generally in the form of capsules; the dose has never exceeded fifty centigrammes (seven and a half grains). As before said, we have never observed any other than hypnotic effects to follow its use, even after months of administration, nor have we been obliged to augment the dose to obtain the same results.

Hypnone must be administered in massive doses; when given in fractional doses its hypnotic effects do not appear; as Huchard found at the outset of his therapeutical experiments. It is essential, also, that the medicament be administered at the moment when the patient ought to go to sleep, and in most of our observations, sleep followed in a period of time varying from half an hour to an hour and a half.

We have made several attempts to introduce this medicament under the skin; it was in cases of obstinate sciatic neuralgia where the irritant local action of the medicament was not to be dreaded, since the worst would have been the production of those substitative effects which are sought for by the method of Luton. In the dose of ten centigrammes the hypnotic and analgesic effects were absolutely nil, but on the other hand, we found that we had provoked a very severe local irritation, contraindicating the further use of this mode of administration. Cases where hypnone has produced no hypnotic result are sufficiently numerous, nor has such effects been obtained by increasing the dose. This is what happened to Filehne of Erlangen, who at my request made trials of this new medicament; in his practice the medicine failed, even in doses of one cubic centimetre. My only explanation of this want of success is the complexity and multiplicity of the causes which provoke insomnia; it depends largely on the cause whether the remedy be efficacious or not.

Given, however, like conditions of experimentation, similar results may always be expected, and if you reserve hypnone for cases of nervous insomnia or for those determined by considerable cerebral excitation, you will in the immense majority of cases obtain good effects from hypnone in doses of from twenty to forty centigrammes (three to six grains) and you may expect exemption from all unpleasant after-consequences.

We think that hypnone ought henceforth to take its place in therapeutics by the side of chloral and paraldehyde, holding a rank inferior to chloral, however, since this acetone is deprived of analgesic properties, but almost equal to paraldehyde. We say almost equal, because in our way of thinking, paraldehyde, which is but slightly analgesic, determines sleep much more markedly than hypnone. We are persuaded that the different clinical and physiological experiments undertaken at this moment with this new medicament will confirm this first judgment.

We have here, then, a therapeutic agent, derived from that aromatic series which has furnished to therapeutics so great a number of medicinal substances, and we are persuaded that in continuing the study of this aromatic series, in the direction of their chemical constitution, we shall find still other substances useful in medicine.

From all that goes before, we think ourselves justified in drawing the following conclusions: (1) Hypnone is a mixed acetone of the aromatic series. (2) This acetone is toxic, and its greater or less degree of purity seems to have a notable influence on its toxicity. (3) Hypnone in toxic dose produces in animals sleep, analgesia, and anæsthesia; it diminishes the

neurility of the nervous elements: lowers considerably the blood pressure, modifies the respiration, and alters the composition of the blood. (4) In a massive dose of from twenty to forty centigrammes hypnone has never produced in man any other appreciable physiological symptom than sleep; it is a hypnotic, especially applicable to nervous insomnia or that produced by alcoholic excesses, or too prolonged intellectual labors.

THE PAVILION IN HOSPITAL CONSTRUCTION.[1]

BY ARTHUR C. HEFFENGER, M.D.,
Passed Assistant Surgeon, U. S. Navy.

A FEW years after the completion of the Lariboisière, the pavilion principle attracted attention in Great Britain, but with that form of generosity so often exhibited in the English character, it was quietly appropriated, and put into execution as an English conception. When in 1860 it was determined to erect the Herbert Military Hospital, it was officially stated that the building would be constructed upon the principles set forth in the "Report of Commissioners appointed to Enquire into the Regulations affecting the Sanitary Condition of the Army, 1858," and the "General Report on the Sanitary Condition and Improvement of Barracks and Hospitals," 1861; and these principles are almost entirely those of M. Tenon, more or less altered to bring them up to the standard of the day, as well as to make them conform to certain insular leanings.

The Herbert Hospital is without doubt a great improvement upon the Lariboisière; the pavilions are only two stories in height; the spacing is much more judicious; the ventilation is freer; and the drainage far better. Indeed the long two-storied pavilions of the Herbert indirectly connected by a central building are far more like those proposed by M. Tenon, than those of the Lariboisière. The Herbert ward, though receiving the almost universal approval of English experts, with Miss Nightingale among them, is nevertheless by no means perfect. It is too long, too low, and accommodates too many patients. The water-closets are too near the sick, and are not separated by cross-ventilated lobbies. The mortuary and separation wards are badly, if not dangerously placed, being in immediate relationship with the free sides of the extreme right and left pavilions respectively.

After the construction of the Herbert Hospital, the new ideas spread rapidly on the continent of Europe, Germany being the first, however, to seize upon and improve them. Between 1868 and 1876 several splendid specimens of pavilion hospitals were erected in various parts of Germany, the first opened, the Friedrichshain Hospital at Berlin, being by far the most complete in construction and appointments. In this type of German hospitals the medical wards are two-storied, and the surgical, one; the water-closets are well separated from the wards, and in fact the arrangements throughout are almost unexceptionable. The Moabite Barrack Hospital, of Berlin, deserves special notice, from the fact that it is the only large hospital of its kind on the Continent of Europe, which is strictly civil. It was built in 1872, sixteen single-storied pavilions being put up in three months, and eight more subsequently added. It was originally intended for infectious diseases, but soon became a general hospital, and, as such, is a pronounced success.

Russia shook off her Asiatic insulation under the scientific stimulus of her German neighbors, and showed her latent capabilities by building the Riga Hospital in the suburbs of St. Petersburg. This hospital was finished in 1873, and is supposed to be built on the plan of the Friedrichshain, but many alterations were deemed necessary, on account of the climate, and these changes have necessarily impaired the sanitary efficiency of the pavilions.

Notwithstanding the great improvements made in the construction and arrangement of pavilion wards in the German hospitals, both Great Britain and France continued to build multiple-storied pavilions, examples of which may be found in the Edinburgh Royal Infirmary, Glasgow Western Infirmary, and the new Hôtel Dieu and Hôpital Tenon in Paris. It is but justice, however, to the medical profession of Paris, to state that they condemned, in unmeasured terms, both these French hospitals, and the *Société des Medicins et Chirurgiens des Hôpitaux de Paris* went so far as to appoint a commission to report upon the new Hôtel Dieu, and the Society, after having discussed the report of its commission, unanimously passed the following resolution: — "As it, at present, stands, the new Hôtel Dieu is so constructed as to be absolutely contrary to the fundamental principles of hospital sanitary law."

The importance of general and special isolation in the treatment of the sick, was early recognized in the United States, and the practical application of the principle was splendidly illustrated in the army tent and barrack hospital, used during the War of the Rebellion. Our civil administrations, however, have been slow to appreciate the necessity for radical change in the usual manner of constructing hospitals, so that we have few built upon the pavilion plan, and the Johns Hopkins Hospital, of Baltimore, is the only one deserving of special notice. This hospital was designed, and is being constructed upon the most modern scientific principles, and much credit is due Dr. Billings, U. S. A., for the able manner in which he is superintending its construction. The design embraces twelve pavilions, only half of which, however, are to be erected at present. Two of the pavilions are octagonal in form, and two stories in height, while the others have only one story above the basement, and are of parallelogram form. Accommodation is furnished for three hundred and sixty-one patients. It is, undoubtedly, one of the best built and arranged hospitals in the world, and were it not for the two double-storied pavilions, and a very questionable location of the water-closets, might be considered well nigh perfect.

In the construction of permanent hospitals upon the pavilion system, two plans have been pursued; first, that of aggregation, or the super-imposition of two or more wards in the same pavilion; second, that of segregation, or the building of wards of one story only, but with the same service attachments as in the pavilion block. Both plans have their advocates among eminent men, but the bulk of opinion is now in favor of each ward being a pavilion hospital in itself, with its own accessories, and separated, as much as possible, from the other wards. It has been held that hospitals consisting of pavilions of one story in height, cover too much ground, and are, therefore, too expensive to erect

[1] Concluded from page 75.

in the large cities, where hospitals are mostly considered necessary; that they are very difficult to administer, and finally, are not any healthier than those in which the pavilions consist of two or more stories. In answer to these objections, it may be said, that hospitals being built, presumably, for the best interests of the sick, should be situated always on the outskirts, rather than in the crowded sections of cities, where their first cost and maintenance would be about the same, whether the pavilions were of multiple or single stories; and when the pavilion block has been reduced to a single ward, which thus becomes an individual hospital, with its own requisite service belongings, it is not easy to see how the difficulties of management can be augmented. As to the comparative healthfulness of the two plans of pavilions, though no positive statistics have been collected to show that pavilions of one story yield better results than those of two or more stories, yet upon sound scientific principles, they should, and it is the earnest belief of the majority of those who have considered the subject carefully, that they do. They can be more easily ventilated; they avoid dangerous over-population of surface area; community of service and atmosphere are reduced to a minimum, and weak patients have no exhausting stairways to ascend.

In determining the form of pavilion ward best adapted to the treatment of the sick, it is necessary to bear in mind the essential conditions to be obtained, namely, a sufficient areage and cubic capacity; an unobstructed flood of light at all times during the day; air in adequate volume, pure, in motion, and of proper temperature; and to ascertain which form most nearly fulfils these conditions with the least amount of artificial assistance.

The parallelogram form in general use, is of very ancient origin, and except in diminution of length, and rearrangement of windows and offices, underwent no alteration until the advent of the *Système Tollet*, to be hereafter described. Just why these long hall-like wards have held such despotic sway over the minds of the medical fraternity, it is difficult to say, unless it is a pure matter of prejudice. They are far from cheerful, awkward to administer; equable heating is all but impossible, and draughts are continuous, and, of course, a constant source of danger. Clearly, with all possible artificial aid, they are far from fulfilling the essential conditions of perfect wards.

The nearly square ward designed by the late Mr. George M. Dexter, of Boston, and introduced into the Massachusetts General Hospital by the trustees, in 1844, and further tried in the erection of a pavilion of one story in connection with that hospital in 1872, is a great improvement upon the old parallelogram, and should not be considered as developed from it. This ward is very cheerful and homelike, admits of almost an equal distribution of heat and light to all parts, is not draughty, and nearly every portion is convenient to the service building. It is a decided step in the right direction, but its corners and flat ceiling materially interfere with ventilation. It was recommended for adoption in the Johns Hopkins Hospital by Dr. Norton Folsom, in his suggestions for that institution.

The octagon ward constructed for the Johns Hopkins Hospital by Mr. J. R. Niernsée, the architect, though fulfilling in the main the same conditions as the square ward, by increasing the number of angles, of course, increases the difficulty of ventilation.

That form of ward which more nearly meets all essential requirements, I hold to be the circular. The great advantages of circular structures, especially when surmounted by domes, seem to have been first discovered by Dr. McKenna, a Scotchman, who happened to be in South America about forty years ago during one of the many revolutions which have repeatedly convulsed the petty republics of that continent, and who had the care of a number of wounded. The patients were treated in convent rooms, which were always rectangular, and in convent churches, which were always in the form of domed circles. Those patients treated in the churches did so much better, indeed marvellously better, than those cared for in the rooms, that he was struck by the difference, and induced to make a close study of the matter. This clever Scotchman soon became convinced that circular structures with domed ceilings were far superior to any other tried form for housing the sick. In 1854, when practising in Melbourne, Australia, he advocated the adoption of circular wards in a large hospital about to be constructed in that city, but without avail. Sir Andrew Clark, who recalled the views of Dr. McKenna before the Hospital Association of London in December, 1884, also related at that time how he had accidentally discovered the automatic ventilation characteristic of the domed circle, while inspecting the grand domed circular tomb at Delhi, in hot, calm weather. He inadvertently let fall from his card-case a small slip of tissue paper, which, to his amazement, instead of falling slowly to the floor was steadily wafted upward to the centre of the dome. Afterwards he made repeated experiments of the same nature in various parts of the circular domed temple at Calcutta, and always with the same result. It is quite evident that there are natural air currents directed upward from all parts of a room thus shaped, though the governing philosophy is by no means clear.

The circular ward was also originated independently by M. Baeckelmans of Antwerp, in 1873, and Professor John Marshall of London, in 1878. M. Baeckelmans's plans were made for the Antwerp Civil Hospital, the corner-stone of which was laid five years before Professor Marshall made known his ideas in a paper read before the Cheltenham meeting of the National Association for the Promotion of Social Science, in October, 1878. M. Baeckelmans's views were the outcome of scientific research, while Professor Marshall's were the result of endeavors to devise a large hospital capable of being placed on the site of the present University College Hospital. In January, 1882, I conceived the idea of circular wards from a study of the octagon pavilions accepted by the Johns Hopkins Hospital management. It occurred to me that a circular ward would not only have all the excellent points of the octagon wards, but would possess in addition greater cubage and areage, and from the absence of angles freer ventilation; and furthermore, when surmounted by a dome all these advantages would be greatly augmented. Knowing that the cost of a building bears a direct ratio to its wall length, it was patent that the circle having a minimum wall length for included areage should be naturally the cheapest structural form. I had never heard of any such form being advocated, and it was not till last year, during a correspondence with Dr. Billings, U. S. A., that I learned of the Antwerp circular wards, and of Professor Marshall's valuable paper.

From a review of the facts previously stated, it is evident that to M. Baeckelmans is due the lion's share of credit for having given to the world, both theoretically and practically, the best form of ward yet devised in which to treat the sick.

The wards in the Antwerp Civil Hospital, and in the Miller Memorial Hospital, at present the only completed types, are by no means as perfect as the system admits. I am convinced that the full benefits can be obtained only in a pavilion of one story, where the automatic ventilation characteristic of the domed circle can be best effected. To summarize; the circular ward surpasses all others in cheerfulness: it allows a flood of light to fall upon the patient from almost every direction; heat may be equally distributed in all parts; in areage and cubage it far exceeds any other geometric form yet used; and with the ceiling in the form of a parabolic dome the air space is vastly increased and ventilation rendered almost automatic.

The circular ward that I designed in 1882 has an inside diameter of 67.5 feet, a total areage of 3,578.47 square feet, and an areage per bed of 147 feet. It accommodates twenty-four patients, who have each 2,425.05 cubic feet of air-space, and 41.5 square feet of window. The ceiling is a parabolic dome, fourteen feet high at wall, and eighteen feet high in centre. Through the centre of the ward passes a heating and ventilating shaft. The ward offices communicate by a folding door, and through them access is gained to the general corridor. A sun-room is placed at a point opposite the offices, and the water-closets are judiciously situated and carefully cross-ventilated.

In England military hospitals at Milton and Seaforth, and poor law infirmaries at Hampstead and Burnley are being constructed with circular wards and Sir Andrew Clark intends building a large hospital with these wards at Valetta, Malta, so that the practical working of the idea under varied conditions will be soon demonstrated.

The system of construction originated by M. Tollet, a noted French architect and engineer, and known in France as the *Système Tollet*, was presented to the Academy of Sciences in 1876. It embraces all the best features of modern hospital construction, but M. Tollet only lays claim to originality in the construction of the inside walls and roofs of rooms in the form of a gothic arch ("*de forme ogivale.*") To do this he forms the sides and roofs of wards with curved wrought iron I – shaped ribs placed about five feet apart, the intervening spaces being filled in below with brickwork, and above with either brickwork, tiling or concrete. The outer surfaces of the ward are finished either with tiles or cement, and the inner surfaces, after being plastered are treated to three coats of oil paint. These wards are still parallelograms, and notwithstanding the gothic ceilings and rounded ends are still open to many of the objections to that form. It is claimed, however, that air never stagnates in them; that heating is easy, and ventilation almost perfect; that they afford ample areage, and enormous cubage; that they are incombustible; and finally, that they can be thoroughly cleansed with either flame or streams of water. The system has been applied to hospitals, barracks, schools, and other public buildings; and M. Tollet has insisted always that the buildings should be of one story only, and raised from the earth upon plinths, with thorough cross-base ventilation. Four hospitals in France, namely: the St. Denis, near Paris, Bichât on the ramparts of Paris, Bourges Military, and St. Eloi at Montpellier, have been constructed upon this system, and are pronounced by those who have inspected them and who are considered competent to judge, to be the most perfect specimens of hospital construction now existing.

CASES OF FUNCTIONAL AND ORGANIC INJURY TO THE CENTRAL NERVOUS SYSTEM, CAUSED BY TRAUMA.[1]

BY G. L. WALTON, M.D., OF BOSTON.

THE cases cited in this paper will serve to illustrate the two great classes, functional and organic, into which nervous injuries may be divided, and to bring out, in a general way, the diagnostic points of practical value.

The name, railway spine, has been long used to cover our ignorance, and many cases of traumatic neurasthenia, and traumatic hysteria have figured, and still figure, as concussion of the spine, myelitis, congestion of the cord, or more vaguely, as spinal injury. It was Page who first called attention to the rarity of organic spinal trouble from trauma without injury to the vertebræ, and the experiences of others, viewed in the light thrown by him on the subject, have confirmed his view that the large majority of the cases upon which claims are based, are functional, rather than organic.

It is important that each case should be put upon its proper basis, and especially, that functional cases should stand upon their own merits, instead of being made to appear incurable and dangerous maladies. Not that these cases should be considered trivial, even though they come under the category of hysteria and neurasthenia, for the sufferings of hysterical and neurasthenical patients are, by no means, necessarily imaginary, and their inability to perform the duties, and enjoy the pleasures of life, may be quite as complete as that of the sufferer from organic disease of the spine or brain. The tendency is, however, to claim, on the one hand, irreparable spinal injury, based on such symptoms as hyperæsthesia of the back and pain on movement, irritable bladder, and at the worst, hysterical paralyses or convulsions; and, on the other hand, trivial damage, the truth lying, generally, between these extremes. The question of simulation will not be alluded to in this paper, although, unfortunately, it plays a large part in the study of these cases.

In a case of this sort, the main questions presenting themselves to the medical expert are, (1) Is the case real or feigned? (2) If real, is the injury functional or organic? (3) What is its exact nature, and what are the chances of recovery? (4) Could such an accident produce such an injury?

[1] Read before the Boston Society for Medical Improvement, January 25th, 1886.

It is only proposed to touch on the second of these questions: Is the injury functional or organic? As illustrations of organic injury, two cases of hæmorrhage into the spinal cord have been chosen, both seen in the Nervous Department of the Massachusetts General Hospital. It will be noticed, by way of diagnosis, that pain in the back, which is almost constant, and very persistent in the functional cases, is either wanting, or only temporary in the organic cases. It will also be noted that subjective symptoms, local pains, emotional tendencies, irritability, insomnia, and allied nervous states, are conspicuous by their absence, while in the functional cases, they play a very considerable part.

The first case is one of unilateral hæmorrhage into the cervical region of the cord, causing paralysis of motion on the side of the hæmorrhage, and of sensation on the other, the paralysis of motion being atrophic in the arm, and spastic in the leg.

Case I. A. G., American, laborer, aged twenty-five, fell, three years ago, from a ladder, about fifteen feet. The ladder fell with him, and he struck against the rounds or sides, so that he was bruised in the cervical and dorsal regions. He did not lose consciousness, but on attempting to rise, found his extremities helpless. Motion improved in the right arm and leg during six weeks; that on the left has remained nearly stationary, after a slight improvement. There was retention of urine for ten days, during which time the catheter was used. There was a sensation of constriction about the abdomen. There was no rectal trouble. The face was not drawn; there was no disorder of speech nor ocular disturbance. At present, there exists a left-sided hemiplegia, with toe-drop, spastic gait, exaggerated knee-jerk, and marked ankle clonus. The flexors, thenar muscles, and interossei of the left hand, are atrophied. There is no loss of sensation on this side. On the right side, there is no loss of motion further than a slight weakness in grip, and other movements of the arm, but there is a loss of sensation over the hand, and outside of the arm, and over the leg and trunk to the median line, extending up to the fourth rib in front, and the spine of the scapula behind. Over this entire area, the head cannot be distinguished from the point of a pin. There is no sensitiveness of the back, or back of neck, no disturbance of memory, or change of disposition. Pain has not been complained of in the back or elsewhere, since the time immediately following the accident.

The second case is, in many respects, similar.

Case II. M. R., thirty-nine, fell, thirteen years ago, from a wagon, striking on the head and shoulders. Motion was lost in all extremities, at first, but in a fortnight, power was recovered in the left arm and leg. Improvement commenced in the right in about a fortnight, and soon power was gained in the right leg, but the paralysis of the right arm, after a certain degree of improvement, remained stationary. There was no loss of consciousness, and no fever. The patient was seen two years later by Dr. Putnam, who found the right arm somewhat smaller than the left, both upper and lower. All motions were possible, excepting those of the muscles supplied by the ulnar and musculo-spinal nerves, but all movements were weaker than on the other side. Extension and straightening of the fingers were impossible. The patient could just manage to touch his thumb and little finger. Degenerative reaction was present in the interossei and extensor communis digitorum. At present, the patient is perfectly well, excepting that there is complete paralysis of the extensors and interossei of the right hand, with loss of electrical reactions. The skin over the extensor aspect of the forearm is colder than that elsewhere. Careful inquiry regarding pain in the back, elicits the fact, that for a few weeks following the accident, there was pain in the back of the neck, and down the right arm, none elsewhere, and none there since, excepting that after severe exertion, he occasionally feels a prickling at the back of the neck. There has been no insomnia, no irritability, no loss of memory, or of ability to confine the attention. There has been no hypersensitiveness to sounds, sights, or movements, in short, no subjective symptom whatever. There has been no sensitiveness to touch of the spine or scalp.

In this case, the hæmorrhage, which was also into the cervical enlargement of the spinal cord, limited itself, finally, to a definite area in the gray matter, so as to destroy permanently, only the motor centres of certain muscles of the right arm and hand. The generalized paralysis at the onset of both cases, was due to the pressure upon other parts of the cord, which was withdrawn with the retraction of the lesion to its final dimensions.

In neither of these cases, was there pain in the back, either spontaneous or on movement, after the first effects of the accident had passed off; and of the immediate pain, it is extremely doubtful how much was due to the hæmorrhage into the cord, and how much to local bruising and muscle strain. In neither case, were mental or "nervous" symptoms present from the first. There were, however, infallible signs pointing to organic injury, namely, atrophy and loss of electrical irritability; and in the first case, ankle clonus, spastic gait, and a distribution of sensory and motor paralysis, which can only be explained by an actual unilateral lesion in the spinal cord.

These organic cases are, however, the exceptions among claimants for damages from falls, blows, and collisions. More common, are those of hysteria and neurasthenia, resulting from the shock, whether to the brain, the cord, or both, or whether to the sympathetic system, through dragging on the intestines, need not be discussed in this paper. In whatever part of the nervous system the injury expends itself, the damage is functional, not organic, and has been aptly compared, by Page, to the result of striking a magnet with a hammer; the magnet remains, apparently, unaltered, but it no longer performs its function. The comparison might justly be carried still farther, for by carefully graduated loading of the magnet, the magnetism may be brought back, although, left alone, it remains permanently inert. Similarly, the nervous system so shattered must, after a reasonable rest, be gradually forced to undertake more and more, or there is danger of the patient's degenerating into chronic invalidism, instead of going on to recovery, which is the result to be hoped for, although not always attained.

The locality of the injury in these functional cases, has been long a subject of argument. The term "concussion of the spine," promises to become obsolete, and even if it does not, such a diagnosis can hardly represent satisfactorily the full extent of the damage, whose symptomatology includes as much mental as physical disturbance. It seems more reasonable to look on the brain as, at least, the principal sufferer, and I ventured, some time ago, in an article on so-called "Spinal Irri-

tation,"[2] to suggest the name "railway brain," to supplant that of "railway spine," intending to include under that title, both hysteria and neurasthenia resulting from trauma.

CASE III. Mr. A., a large, stout man of about fifty-five, was thrown, with some violence, from a horse-car, striking on his hands and knees. He was kindly referred to me, some months after the accident, for treatment of his nervous symptoms, by Dr. Porter, under whose care he was at that time. Withdrawing from his complex of symptoms those which concern us here, we find him, at this time, extremely nervous and irritable, unable to concentrate his attention, or to think continuously. He is extremely sensitive to the slightest jar of the body, driving over the smallest obstacle seeming to cause him great distress. He has complained of pain and stiffness of the back since the time of the injury, and holds his back stiffly in sitting and walking. There is hyperæsthesia of the back, and certain spots on the limbs are so sensitive, that the lightest touch elicits signs of pain. The knee-jerk is greatly exaggerated. There is no atrophy, no paralysis, motor or sensory, no change in electrical reactions, no pupil irregularities, ankle clonus, nor other sign of organic lesion of the brain or cord. The symptoms are said to have dated from the accident, and there is no reason to doubt the fact, especially as there is no thought of claiming damages.

There may have been, and probably was, a predisposing tendency, in this patient, to functional nervous disease, although no special nervous family history was made out. Whether there was or not, the fall may be fairly considered the immediate cause of the symptoms, which have gradually improved. This case should be classed as traumatic neurasthenia, if we limit the term hysteria to cases presenting marked disturbances of sensation, motion, circulation, and the mind. This classification leaves mere nervous irritability and exhaustion under the head of neurasthenia. It is, however, neither possible nor necessary to make an accurate classification, in each case, between hysteria and neurasthenia. Both are, practically, functional diseases, and both may be produced in either sex, by a physical shock, in persons either predisposed, or not predisposed.

The stiffness and pain in the back on movement, in this case, probably represented the remains of a strain of the muscles of the back, and possibly, the ligaments of the spine. The duration of this symptom may be almost indefinite where the effort of breaking in the muscles by enforced exercise is neglected, especially if sensibility to pain is increased by the neurasthenical element, and most of all, if an artificial support, as a plaster-of-Paris jacket, is worn to relieve the muscles of the trunk. Pleasant as may be the temporary comfort of such treatment, its effect is, probably, to postpone recovery by over-favoring the weakened parts.

As examples of the possible, though exceptional, duration of such symptoms, I may mention two patients I have recently seen, each of whom brought on the trouble by lifting too heavy a weight, and favored it by subsequent exposure. In one case, the sensitiveness, pain, and stiffness of the back, supplemented by nervous prostration, has lasted over twenty years, and in the other, fifteen. The former is a claimant for a pension, but the latter claims no damages of any sort, but has worn, notwithstanding this fact, an elaborate artificial support for the past six years, without which, he says, he can neither work nor enjoy himself. I have strongly urged its gradual discontinuance, with regular gymnastics, and other tonic treatment, but whether the patient will summon the necessary strength of will, is a question for the future. In both these cases, organic diseases of the spine and vertebræ were carefully eliminated.

The following and last case may be classed under traumatic hysteria. It was referred to me for an opinion on the nervous element, through the kindness of Dr. Porter and Dr. Marcy, who had been consulted respectively, by the defence and the plaintiff.

CASE IV. J. M., twenty-three, who was well previous to the accident, was thrown about violently by the derailment of the car in which he was riding, the car rolling over down an embankment. He was able to get up and assist others, at first, but soon gave up, and remained ten weeks in bed. Headache and backache were severe and constant. There was retention of urine for a short time. In the notes of my examination, eighteen months later, and just before the trial, I find the following: Loss of sexual power is claimed to have existed since the accident. Improvement has been gradual and steady up to this time. He now complains of quite severe headache, generally at the vertex, with a burning sensation, and of pain in the entire length of the back, increased on motion. He walks stiffly; stooping forwards causes pain in the back and thighs. There is exaggeration of tendon, plantar, and abdominal reflexes. There is a tender spot at the vertex, and tenderness to the touch all along the spine, most marked in the upper dorsal, and in the lumbar region. Pressure over these spots causes an almost convulsive retraction of the back into an opisthotonic position. There are no other sensitive regions. He wears a plaster-of-Paris jacket, which seems to afford much relief, and to facilitate movement. There is anæsthesia of the legs, evenly distributed, and extending to a definite line around the trunk from the lumbar region. Over this entire region, pressure must be moderately severe before it is felt, and all stimuli must be excessive before causing pain. There is slight paresis of all movements of the legs. There is no bladder or rectal disturbance, no atrophy or coldness, no ankle clonus, no loss of electrical reaction; the legs are plump, and are of about the same size, by measurement. There is no disturbance of special sense, the pupils are alike, and react normally. My notes make no statement of his mental condition, but I have the impression that he complained of inability to confine the attention, and apply himself to continuous mental labor. There was a dislocation of the outer end of the left clavicle.

In this case, there existed definite loss of sensation and motion, which could only be of functional origin, considered in connection with the other symptoms. It should, therefore, be classed under hysteria. The persistence of the symptoms, in no wise militates against hysteria, a fact to which Charcot[3] has drawn particular attention, of late, in a lecture on hysteria in the male. Cases are certainly not rare in which symptoms of undoubted hysterical origin have lasted years, without material change.

My opinion, which did not include the surgical injury, beyond disconnecting it from the nervous trouble,

[2] Boston Medical and Surgical Journal, Dec. 27, 1883.

[3] Progr. Méd. 1885, No. 18. Reviewed in Neurolog. Centralblatt, June 1, 1885.

was that the patient was suffering from, (1) the remains of strain of the muscles of the back, and, perhaps, of the ligaments of the spine; and (2) hysteria, brought on, probably, by the shock to the nervous system, and evidenced, mainly, by hyperæsthesia of the back, and anæsthesia and paresis of the legs. The chances for recovery I considered good, provided the patient should make the necessary effort.

The sympathy excited by the sensitive back, and the plaster-of-Paris jacket, in this case, was, evidently, not inconsiderable, and the view of the case presented by the plaintiff's counsel, seemed to be, that loss of sensation in the legs, extending to a certain height on the trunk, must point to serious disease of the spine, at that height, and that the case would terminate in permanent and total paralysis. However far from the facts of the case this view may have been, it was not so absurd, after all, that it should be advanced, when we consider the hazy ideas which have long existed, even among the medical profession, and medical authorities, regarding the symptomatology, course, and prognosis of so-called "railway spine."

Hospital Practice and Clinical Memoranda.

A CASE OF TRACHEOTOMY IN A NEONATUS.

BY H. H. HANSON, M. D., OF ANDOVER, VICTORIA CO., NEW BRUNSWICK.

NOVEMBER 7th, 1881, was called seventeen miles to see a patient who had been in labor three days, and as yet undelivered, although attended by three "*Meddlesome Midwives.*" On my arrival, I found patient apparently happy and contented, as the French generally are, under the most adverse circumstances. Lying prone on the floor, and surrounded by seven women and three of the "male persuasion," two of whom were enjoying the never to be lost sight of fumée; besides "enfants," innumerable.

During the patient's labor she informed me that only a small quantity of broth had passed her lips. I learned subsequently, that during the three days, she had taken about three gallons of pork and pea soup. The child's head had been born about thirty minutes and no pulsation in fontanelles could be detected. Lividity of features, cord around neck, and non-rotation of shoulders. The latter caused the non-success of the female obstetricians. The shoulders of the fœtus being rotated into position and the hook of a Hodge forcep introduced into axilla, delivery was instantly affected. Child's buttock was spanked, alternately sprinkled with cold and hot water. Before cord was ligatured a few drops of blood had been allowed to flow.

Artificial respiration was resorted to, for the period of thirty-five minutes, but all to no purpose. I was about giving up in despair when I thought of a trocar and canula I had in my instrument case (one used for Hydrocele). Placing a small stick of beech under shoulders of fœtus so as to throw the head back and raise the chest, I plunged the trocar and canula into trachea, and thoroughly inflated the lungs, which was in a few minutes followed by expiration, produced by compression of thorax. This procedure was maintained for about fifteen minutes, when to my satisfaction, I could faintly hear a struggle for existence. This was followed by more, until at last it was life, "in all its forms." The canula was taken away soon after, and a suture introduced through integument, and a piece of lint soaked in cold water applied, and kept on by means of adhesive plaster. The child made a good recovery, and is to-day fast becoming able to take its place at the hospitable board of its parents, amid the fearful havoc of pea and pork soup, buckwheat plugs, and "boudan."

REPORT OF PROGRESS IN GYNÆCOLOGY.

BY F. H. DAVENPORT, M.D.,
Assistant in Gynæcology, Harvard University.

OPERATION FOR THE CURE OF STERILITY IN CASES OF CONICAL CERVIX, WITH FLEXION OF THE CERVIX UTERI.

DR. GRAILLY HEWITT[1] describes a new operation for sterility in that class of cases characterized by a conical, elongated cervix, with flexion of the cervical canal, a condition described by Emmet as anteflexion of the cervix. He considers this condition due to imperfect nutrition, loss of tone, and gradually increasing bending of the cervix, which changes occur subsequent to puberty. The principal methods of operation hitherto recommended have been amputation of a portion of the cervix, and the posterior incision, as recommended by Emmet and Sims.

The operation which Dr. Hewitt performed in one case, was as follows: Having drawn down the cervix, he removed from the posterior aspect, in the median line, a portion of mucous membrane nearly an inch in length, and half an inch wide, and having done this, stitched the upper and lower margins together, the effect of the procedure being to shorten the vaginal cervix on its posterior aspect, to draw the os uteri backwards, and thus straighten the vaginal cervix, and increase its patency. When the stitches, three in number, were tightened, the vaginal cervix was made to look downwards, instead of upwards. The sutures were removed after a few days. Conception followed in the course of a few months after the operation.

He considers this operation an improvement upon the two other methods, because the uterus, as a whole, is less mutilated, and presumably, its functions may be supposed to be better exercised when the cervical canal and the os uteri externum are preserved.

ON HYSTERECTOMY.

Dr. Thomas Keith,[2] in this paper, while recognizing the marvellous improvements and results of the last ten years in operative interference in cases of fibroids, yet takes a thoroughly conservative view, and advises the operation of hysterectomy only in extreme cases. The removal of the ovaries and tubes, he says, is an operation full of promise, and, as regards his own work, the result is more satisfactory every time that it is performed. It will not, however, supersede hysterectomy, as there are cases in which, even when got at, the ovaries cannot be separated from the uterine tumor without too great a risk. He advises trying the simpler method first, in all cases where the tumor is small, and

[1] British Medical Journal, June 13th, 1885.
[2] Edinburgh Medical Journal, May, 1885.

does not extend much above the umbilicus. The proportion of cases in which interference of any kind is warrantable is, perhaps, not greater than five per cent. The cases in which he thinks hysterectomy may reasonably be recommended are these:

(1) In very large, rapidly-growing tumors of all kinds in young women.

(2) In all cases of real fibrous cystic tumors.

(3) In most cases of œdematous fibrous tumors which are not cured by removal of the ovaries. They occasionally grow to be very large, even weighing two hundred pounds, according to the author. Sometimes, large quantities of red serum can be removed with much relief, and in this way, the patients carried over the menopause, when the necessity for further puncturing ceases.

(4) In cases of large, bleeding fibroids, when removal of the ovaries cannot be accomplished, provided that the patient is not approaching the menopause. In these cases, as a rule, though there are many exceptions, menstruation goes on much beyond fifty.

(5) In certain cases of tumors surrounded by much free fluid, the result of peritonitis, provided that the fluid shows a tendency to reaccumulate after two or three punctures. Occasionally, when the fluid does disappear, its absence may, from some change in the osmosis, be followed by an extremely rapid growth of the tumor. It is important to remember that long-continued irritation of the peritoneal surfaces by large, solid tumors, is apt to be followed by degeneration of the peritoneum of a sarcomatous or cancerous nature. The microscopic examination of the fluid will, in such cases, keep one from falling into error. Dr. Keith has several times, where large, healthy, uterine fibroids were present, removed fluids swarming with cancerous elements, the source of which was found to be altogether in other organs affected with cancerous disease.

Then follow the histories of several operations, which are of use in showing the different ways of treating the attachments of uterine fibroids, or illustrating some other point of interest.

TREATMENT OF THE PEDICLE IN HYSTERECTOMY.

Pozzi [3] says the treatment of the pedicle in hysterectomy, must differ from that in ovariotomy. First, because septic infection can take place through the cervical canal; and second, because the absolute prevention of hæmorrhage is very difficult. He makes the following propositions:

(1) When the cavity of the uterus is not opened, and there is slight hæmorrhage from the pedicle, the intra-peritoneal treatment of the stump should be employed, after careful suture of the edges of the wound, with insertion of the peritoneum, according to Schroeder.

(2) When the uterine cavity is opened, and the pedicle is too short and thick for the extra-peritoneal method, and there is moderate hæmorrhage, the stump should be dropped after ligaturing with silk.

(3) When the uterine cavity is opened, and there is slight hæmorrhage, and the pedicle is long enough, the extra-peritoneal method is to be preferred; here, the elastic ligature is a useful adjunct.

(4) For long pedicles which have a tendency to bleed, the extra-peritoneal treatment is best, and the elastic ligature alone gives security against hæmorrhage.

(5) With short pedicles which bleed freely, whether the uterus has been opened or not, the intra-peritoneal method is necessary; the elastic ligature is here, also, the only safe method.

(6) Numerous observations (Olshausen, Hegar, and Kaltenbach, Ahlfeld, Fischer), have shown that the elastic ligature can be left without injury.

(7) The temporary use of elastic ligatures aids greatly in the removal of all abdominal tumors. By tying a temporary ligature around the pedicle, and, if necessary, two others around the broad ligaments, one can operate almost bloodlessly.

ALEXANDER'S OPERATION FOR RETROVERSION OF THE UTERUS.

This operation, which was first brought prominently before the profession in 1883, by Alexander, is gradually becoming a recognized operation in Great Britain. It has been performed a few times in this country. It consists in exposing the round ligaments at the external ring, drawing them out, and shortening them, thus lifting the uterus. They are then secured by sutures in the new position, and the organ is held in anteversion.

Dr. W. M. Polk,[4] in a lecture on this subject, gives a history of a case, with some interesting hints as to the method of operating. The patient, who had been a sufferer for years, especially since her last confinement six years previously, was found to have a retroverted and flexed uterus, the body being felt low down in Douglas's cul-de-sac. Cotton pessaries, and other forms had been tried, but abandoned on account of pain and tenderness. The operation in question was, therefore, performed, and was successful in retaining the uterus in its new position.

In commenting on the operation, Dr. Polk refers to the ease with which the external ring is found in the male, and says the conditions are so different in the female, owing to the thick layer of adipose tissue, that it is only after incising the skin, adipose tissue, and superficial fascia, that the external ring can be clearly made out in many cases. Nor is the ligament a well-defined cord. Passing directly beneath the arch over the canal, is seen some tissue resembling unstripped muscular structure, which is vascular, intermixed with fat. This is really the extremity of the cord, and by traction on it, the cord will be brought to view.

A danger to be kept in mind, is sloughing and retracting of the cord within the abdominal cavity. This is due to the cutting off the vascular supply, which comes from two sources; a branch of the ovarian artery, which supplies most of the ligament, and a branch of the deep epigastric, which supplies the extremity. If too much traction is exerted on the ligament, or the extremity is tied too tightly, there will be interference with the circulation, and this accident may occur. Traction may be lessened by holding the uterus up with a cotton tampon or pessary, and the other difficulty may be avoided by passing the stitches longitudinally to the cord, and not bisecting it.

ARTIFICIAL SUPPRESSION OF THE MENSES.

Loewenthal,[5] in a paper read before the Fifty-eighth Meeting of the German Naturalists and Physicians, at Strassburg, attempts to show the practical side of his new theory of menstruation. He first speaks of the

[3] Centralblatt für Gynäkologie, No. 39, 1885.

[4] Philadelphia Medical Times, August 22, 1885.

[5] Centralblatt für Gynäkologie, No. 40, 1885.

method of suppression of the menses, which consists in rest in bed, and hot-water injections. These should have a temperature of 50° C. (preferably, more), as he has observed that at a temperature of 46–47° C., they favor hæmorrhage. The rest in bed should be maintained for some time after the cessation of the flow. In a few cases, he has found cold water more effectual than hot in checking the menstruation. Then follow the details of twenty-three cases, which he had the opportunity of observing for a long time. Eighteen of these were well-marked cases of chronic chlorosis and anæmia, with very troublesome nervous complications, such as severe nervous dyspepsia, general hysterical symptoms, hysterical convulsions, and two cases of hystero-epilepsy. Of the remaining five, two were cases of marked hysteria, and three convalescent from debilitating diseases. In the case of these last, a quicker convalescence was the object of the treatment, and the author thinks it was attained. In the eighteen chlorotic cases, marked improvement began directly after the first suppression, without any other medication, and recovery occurred after from the second to the eighth. Of the two cases of hysteria, one became much better, the second not. In all these cases, the nervous, dyspeptic, and hysterical symptoms appeared after the beginning of menstruation, and were worse at each period Loewenthal has never seen any bad results follow this treatment.

ONE HUNDRED AND SIX LAPAROTOMIES.

Dr. William Tauffer [6] gives the results of the one hundred and six laparotomies which he has performed. He groups the cases according to their anatomical relations, and in the first section, gives the details of fifty-nine ovariotomies. Of these, fifty-four recovered, and five died, giving a mortality of eight and a half per cent. The cause of death was septic infection in three of the cases. In one of the fatal cases, the tumor, in its development, had not only reached the uterus, but had, apparently, so acted upon its muscular structure, as to cause a hypertrophy of it, and an intimate growth of the cyst with the uterus. The cyst could only be separated with great difficulty, and left a surface robbed of its peritoneum, and liable to bleed. Hæmorrhage was the cause of death in this case. In two subsequent similar cases, he performed hysterotomy, as well as ovariotomy, with good result. In thirty-one cases where there was a well-marked pedicle, only one died; in nineteen with broad attachment, there were three deaths. In four cases, in which it was impossible to remove the whole cyst, he stitched the remaining portion to the abdominal wound, and drained through Douglas's pouch.

The second series comprises seventeen castrations, with no deaths. Twelve of them have already been published in the *Zeitschrift für Geburtshülfe und Gynäkologie, Band IX, Heft.* 1.

Of the third series, which comprises hysterotomies and myomotomies, seven cases were operated on with intra-peritoneal treatment of the stump, and of these, four died. A series of seven cases, where the pedicle sewn into the peritoneal wound was treated with chloride of zinc, recovered. In cases where the pelvis is so filled with the tumor, that it is impossible to remove it wholly, he recommends a combination of hysterotomy and castration. Having shelled out as much of the tumor as possible, he removes the ovaries, and applies chloride of zinc to the stump. In this way, large masses of the tumor gradually come away.

The fourth series comprised fifteen exploratory incisions, in ten of which there was malignant disease, and the tumors were not removed. Twelve of the fifteen died; ten in consequence of the character of the disease, and two from loss of blood.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

January 25th, 1886, the President, Dr. F. W. Draper, in the Chair.

Dr. F. C. Shattuck briefly reported as follows:

A CASE OF ESSENTIAL PERNICIOUS ANÆMIA.

M. C., sixty years of age, married, and the mother of several children, entered the House of the Good Samaritan, November 4, 1884. She was a woman of large frame, had always been very well and strong, and had been able to lift a barrel of flour, when younger. For some time, she had been a cook in a restaurant. Her symptoms were those of anæmia and debility, and dated back for, perhaps, a year, though she had worked till shortly before entrance. There was also moderate bronchitis. Under treatment, she gained six pounds in weight, and improved so much that, after two or three months, she was sent to St. Luke's Convalescent Home. There she grew worse again, and was re-admitted to the Samaritan in April. During the spring she was so ill that there seemed, at one time, but small hope of her recovery; but improvement set in, and in August, she was discharged, and went again to work. After working four weeks, she was obliged to give up, and went again to St. Luke's, but, steadily losing ground, was again transferred to the Samaritan, October 15th. After this, she was confined to the bed till her death, January 22d. The marked symptom was anæmia, with inappetence, occasional nausea and vomiting, and attacks of diarrhœa, which yielded readily to treatment. Arsenic, which seemed to have done her good service when she first entered the Samaritan, was given without success, as were several preparations of iron, and other tonics. During a fortnight, dialyzed iron, m. xx–xxx, was given daily, subcutaneously. One abscess, and some hard, painless nodules, not tender on pressure, which were found, after death, to contain iron, resulted. There was, at no time, fever or hæmorrhage, and repeated careful physical examination always gave negative results, except that some enlargement of the heart, with a systolic murmur, probably hæmic, was made out. I regret to say, that an examination of the blood, though frequently contemplated, was never made.

In the absence of any local disease, as well as could be determined, to which the anæmia could be attributed, the diagnosis of primary, or essential pernicious anæmia, was made, and was fully confirmed by the autopsy, which was made twelve hours after death, by Dr. Fitz, who will kindly show the specimens. No cause for the disease, apart, possibly, from overwork, was ascertained.

DR. FITZ described, as follows, the conditions found after death: The skin was pale, of a faint lemon-yellow color, and the fat tissue throughout the body was abundant. The head was not opened. The heart was slightly enlarged, and showed extensive spotted fatty degeneration of the wall of the left ventricle. The blood was pale-red, and liquid. The gross appearance of the spleen indicated nothing abnormal, and its dark-red color was strongly contrasted with the pallor of other organs. On microscopic examination of scrapings, large and small red blood-corpuscles were found, and, occasionally, others of irregular shapes. Large finely-granular corpuscles, with red blood-corpuscles as contents, were rarely met with.

The kidneys were slightly atrophied, and contained abundant pigment granules. The liver was somewhat atrophied, the section of a uniform brownish color, the lobular regions indistinctly marked. The peripheral cells contained a moderate quantity of small fat drops. The common duct was obstructed with mucus. There was nothing noteworthy in the appearance of other organs, with the exception of the bones. The marrow of the fibulæ was uniformly red and translucent, the so-called lymphoid marrow. On microscopic examination, large, red blood-corpuscles were seen, of the size of marrow cells. They were often nucleated, the nucleus sometimes resembling the corpuscle in color, but more refractive; in other cases, they were granular, with a sharply-defined, annular border, resembling the nuclei of marrow-cells. The nuclei of the red blood-corpuscles were occasionally, nodular, suggesting a tendency toward subdivision into two or three smaller bodies. Numerous marrow-cells were found, containing one, two, or three small red blood-corpuscles. In addition to the above-described macrocytes, numerous minute red blood-corpuscles were seen. Multiform red corpuscles were numerous, biscuit-shaped, club-shaped, and caudate. Charcot's crystals were not seen.

The microscopic examinations were made on the day following the post-mortem examination.

DR. J. B. AYER reported a case of

CO-EXISTENCE OF SCARLET FEVER AND VARICELLA IN A CHILD TWO AND A HALF YEARS OLD.

A case of this kind, now under his care, has interested him, as John Hunter taught the doctrine, that the eruptions of two fevers cannot co-exist, and Hebra stated that he had never seen two forms of exanthemata in the same individual, at the same time; and did not believe that any one could furnish proof of its occurrence.

However, it is generally admitted, at the present time, that the co-existence of eruptive diseases is *possible*, although few cases have been reported. The patient, a boy, two and a half years old, was bathed at 11 A. M., January 9th, by a careful and experienced nurse, who saw no eruption upon the body at that time, being then on the lookout for eruptive diseases. He remained well until 10 P. M., the same evening, when he became restless and feverish, and vomited. At daybreak, a fine, uniform rash appeared upon the face, neck, chest, and back, quickly extending downward. At the same time, varicella vesicles were seen on the trunk, and their number multiplied rapidly. There was pruritus, caused, apparently, by the rash, and not by the vesicles. The fauces were reddened. The temperature, the first day, was 101.5°.

The rash was present three days, the highest temperature, during this time, being 102.2°. Later, the temperature did not rise above 99°. Crops of new varicella vesicles kept constantly coming out, till the end of the fifth day. January 16th, seven days from the outset, bran-like desquamation was noticed on the chest, followed, in a few days, by shreddy desquamation of cuticle; principally, upon the palms of the hands, and upon the fingers.

This is the ninth day of desquamation, and shreds of cuticle are still separating. It is probable that the process of desquamation will require another week. Unquestionably, in this case, the eruption of a mild form of scarlet fever has co-existed with that of a typical form of varicella *from the outset*.

As far as Dr. Ayer could determine, one disease has not been modified by the other.

RAPID ŒDEMA OF THE LARNYX.

DR. EDES reported the case of a man, aged thirty-five, an athlete, in excellent health, who was exposed to cold on Tuesday; on Wednesday, had a chill, but went to business, returned early, and was seen in the afternoon, hoarse, complaining of great difficulty in swallowing. Fauces red, but not much swollen. No swelling of the tonsils. The next morning, the appearances were about the same, the voice almost gone, swallowing very painful. A few hours later, he jumped out of bed, said he was suffocating, ran through the entry, making a noise, which, from the description, seemed to have been that of obstruction to inspiration, and died in a few moments.

At no time previous to the final attack, had there been any complained-of difficulty of breathing, nor had dyspnœa been noticed by the attendants. The autopsy showed œdema of the epiglottis, and of the vocal cords, and neighboring parts of the larynx. There was considerable mucus in the bronchi.

DR. GANNETT who had made the autopsy, described the appearances found, which consisted of a marked degree of œdema of the submucous connective-tissue of the epiglottis, aryepiglottic fold and glottis. The appearance of the mucosa of the pharynx, larynx, trachea and bronchi had been so modified by the use of a preservative that no conclusions as to its condition during life could be drawn. The appearances in general were those of death by suffocation.

DR. HOOPER called attention to his report in the *Boston Medical and Surgical Journal*, July 24th, 1884, containing mention of Mr. Jonathan Hutchinson's view, that catarrhal laryngitis is a very definite affection, common in the milder, rare in its severe forms, depending upon exposure to cold, and rapidly and completely passing off if the patient survive; but when severe enough, attended by paroxysms of dyspnœa, which are occasionally rapidly fatal. One report of an autopsy is given, made within an hour of death, in which the larynx and adjacent parts were in a state of extreme congestion, with much œdema, but without a trace of membrane.

DR. MINOT reported a case of

CHRONIC DISEASE OF THE KIDNEYS AND BLADDER.

THE patient, a man forty-five years old, entered the Massachusetts General Hospital, under Dr. Minot's care. He had had repeated attacks of fever and ague ever since childhood, with occasional attacks of pain, swelling and redness of the wrists, insteps, fingers and toes. He had had stricture of the urethra for twenty years. There were tophi in the helix of one ear. The

urine was alkaline, sp. gr. 1014; containing three-fourths of one per cent. of albumen, much pus, waxy casts, much renal and bladder epithelium, and crystals of triple phosphate. He became maniacal, and then comatose, and died in about ten days after entrance.

Dr. Fitz who had made the autopsy, reported its chief features. Œdema of both lungs was present. The heart was not hypertrophied, and the spleen was no larger than that of a child seven years of age. Its artery was small, and its cut surface did not show any special prominence of blood vessels or vasculæ. The follicles were distinct. Moderate amyloid degeneration of the smaller arteries was discovered on the application of iodine. There was amyloid degeneration of the intestines, but none of the liver.

The genito-urinary organs were the chief seat of the disease. There was an old stricture of the membraneous portion of the urethra about a third of an inch in circumference. The surface of the urethra was rough and white in the vicinity of the stricture, from the abundant formation of epidermis. The spongy bodies of the urethra were intimately connected with the perineal skin by dense and contracted fibrous tissue.

Behind this stricture the urethra was moderately dilated and the walls of the bladder were thickened to the extent of half an inch, chiefly by diffuse hypertrophy of the muscular coat. The mucous membrane was thickened and injected and the bladder was firmly contracted, its cavity containing about an ounce of offensive dirty-gray fluid. The ureters were not dilated, and their mucous membrane was of normal appearance. The left kidney, somewhat larger than normal, presented the characteristics of large white kidney and showed extensive amyloid degeneration. The right kidney was about one-fourth the size of its fellow; the diminished size resulting chiefly from the atrophy of all the pyramids excepting two, in consequence of chronic pyelitis over the atrophied portion of the kidneys. The perinephritic fat tissue was indurated and intimately adherent. Amyloid degeneration was present and the right renal artery was diminished in calibre at its origin, from chronic endarteritis, the evidences of which were also visible along the aorta. The anatomical diagnosis was stricture of the urethra and periurethritis, diffuse hypertrophy of the bladder, cystitis, diffuse nephritis, chronic pyelonephritis, amyloid degeneration of the kidneys, spleen and intestine, aplasia of the spleen.

Dr. G. L. Walton read a paper entitled

CASES OF FUNCTIONAL AND ORGANIC INJURY TO THE CENTRAL NERVOUS SYSTEM CAUSED BY TRAUMA.[1]

Dr. Webber said that he thought Dr. Walton does well in making the distinction that an excess of subjective and emotional symptoms belongs to functional and not to organic disease. He mentioned the case of a man who was injured upon a railroad two years ago, and whose right arm was affected by a twist or strain, the right leg being also affected. There is some loss of sensation which might be taken for functional, with more or less shamming, but that there is also a partial loss of electrical reaction. We know that the strain or twist causing a sprained ankle does mischief that may last during life, the patient being now better, now worse. There was here probably a similar strain of a nerve and its most probable seat was in the spinal canal.

[1] See page 102.

Many cases of traumatic injury to the nervous system are undoubtedly central. The speaker referred to the effect of shock as probably sometimes causing disturbances of nutrition from which the patient may be a long time in recovering; or such disturbances may end in scleroma instead of in recovery. He illustrated his meaning with the case of a patient who for four and a half years after all damages had been settled, could not move his leg, but who nevertheless got well. We cannot say why this was, but disturbed nutrition would account for it.

Dr. A. H. Nichols said that in view of the difficulties in the way of diagnosis, and the impossibility of being absolutely sure, when such cases came before the courts great attention should be paid to the reputation of the patient for veracity.

Dr. Edes was glad that Dr. Walton had emphasized the cases in which organic lesions existed, for the reason that since the appearance of Dr. Page's book, the tendency had been to consider nearly all cases of "spinal concussion," "railway spine," etc., either feigned or hysterical. He had seen several cases in the hospital[2] where he had supposed from the presence of ankle clonus, spastic gait, etc., that organic disease of the postero-lateral columns existed. In one case where a man fell on his back across a wheel, and contraction of the upper limbs with paralysis of the lower resulted, he confidently expected to find a fracture, but there was none. The postero-lateral columns, however, were found to be sclerosed.

Dr. Folsom spoke of the difficulty in making a differential diagnosis between organic diseases in which the anatomical changes are slight, on the one hand, and those which are classed as functional (hysteria and neurathenia) on the other hand, especially as regards giving an opinion as to probabilities of recovery. He believed slight disseminated sclerosis to be quite common in many cases of so-called railway spine, for instance, as has recently been stated by Westphal.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Annual Meeting held at the Carnegie Laboratory, January 18, 1886.

ELECTION OF THE OFFICERS.

The following officers were elected for the ensuing year: — President, Dr. Charles A. Leale; Vice-President, Dr. John Shrady; Recording Secretary, Dr. P. Brynberg Porter; Corresponding and Statistical Secretary, Dr. Glover C. Arnold; Treasurer, Dr. E. S. F. Arnold; Members of the Executive Committee, Drs. John H. Hinton and G. S. Wood.

Dr. Lawrence J. McNamara read a paper entitled,

A STUDY OF THE ETIOLOGY OF TUMORS.

The existence in the body of an independent growth, distinct in its histological elements, from the surrounding matter, drawing nutriment from the general system, and liable at certain periods of development to infect the organism, he said, had always been a perplexing, though fascinating subject to the observer. Advances in histological work had enabled us to make a partial classification of these new growths, according as they were formed on some type of existing normal

[2] See Boston Medical and Surgical Journal, September 14, 1882.

tissue, as epithelial, muscular, nervous, or connective tissue. The group of neoplasms under which were ranked tubercle, syphilis, glanders, etc., had a distinct place as formations of an infectious origin; and were no longer considered as tumors similar to those now under discussion.

The class of tumors formed after types of normal tissue which are most frequently brought to the notice of the surgeons, were sarcoma and carcinoma. These were distinguished by secondary formations, or metastases, and the tendency to recur, from tumors of a benign character. These metastatic or secondary deposits bore the same relation to the structures in which they had found a resting place as the parent tumor. They assumed the changes in growth, development and invasions of organs, identical with the primary growth. The channels of infection were the lymph and the blood. In the ordinary cases of carcinoma, examination of the advancing mass showed infiltration of the normal tissue by epithelial cells. The lymphatics were found plugged with epithelial elements, and the glands contained the same distinct cells. In this formation, at least, it was unnecessary to imagine a virus, transmitted to the body from without, as the cause of the proliferation. There could be no doubt of the malignancy of cancers. The metastases, however, were always of epithelial formation, similar to the primary cancer, and the epithelial cells resembled one another in shape and appearance. The important fact lay in the misplaced epithelial cells. Like the forms of vegetable life, the cell was influenced in its activity by the nutriment which surrounded it; and a modification of this condition would lead to a change in its activity. The epithelial cell if placed in a tissue receiving more nutriment than its own, must, undoubtedly show some changes in its activity. The transplanting of the spur to the comb of a cock was a familiar example. In some cases of cancer of the breast it seemed to him that he could make out a distinct connection between the swollen epithelium of the duct and the cells beyond; and this fact had been mentioned by others also. The epithelium in the connective tissue and the duct, seemed identical in form and appearance.

The diagnosis of cancer could not be made until the epithelial cells formed nests in the connective tissue. If this epithelial element did not come from the proliferating interpapillary processes, it might have existed previously; and to suppose this was to admit the embryonic theory of Cohnheim. The arguments advanced by its originator, offered very convincing proof of the etiology of many complex tumors, like the sacral teratomata, the mixed tumors of the parotid, dermoid cysts, etc. Applied to the sarcomatous group of tumors, the theory had no direct proof of their embryonic origin. There could not be as much reason for accepting the belief that the epitheliomas of the lips, pylorus or rectum, originated from an embryonic epithelial cell displaced and started in growth by continued irritation, as for believing that the irritant might cause the invasion of the connective tissue by the proliferated epithelial elements.

In sarcomatous growths more difficulty was experienced in accepting this embryonic theory. Until proof could be furnished that these embryonic cells existed in the body and developed into a distinct tumor under favorable circumstances, the theory of Cohnheim could not be logically entertained. The transplanting of embryonic cartilage to the adult animal, and its development into a tumor, had been thought to prove the fact of the power of embryonic cells to live and multiply in a mature matrix. It was conclusive, however, that the embryonic cells would grow in the mature organism under favorable conditions. Another difficulty in determining the embryonic foci was the similarity under the microscope of embryonic cells, the round cell of inflammation, and the small cell of sarcoma.

DR. MCNAMARA went on to say that the perplexing view of predisposition as the cause of tumors was found in many of the theories, and that it served the purpose of hiding their defects and increasing the obscurity in which the course of their neoplasms lay. Malignant growths had often been compared to the infective granuloma in their course and development. The changes which occurred in these infective neoplasms, such as necrosis and the like, might find counterparts in the malignant deposits of tumors. Clinically, there were other points of resemblance: but the infective granuloma, besides possessing the power of invasion of tissues, might be inoculated. Clinical efforts or experimental works had never been able thus far to connect a bacterium with the cause of tumors.

Still the infectious origin of sarcoma offered at present great attractions. The discovery of a vegetable growth as the cause of actinomycosis had some bearing on this subject; and the tumors these actinomycoses caused, were called, before their parasitic nature was proved, osteo-sarcoma, tuberculous tongue, etc. Sarcoma, when rapidly growing, presented changes of a similar character in the reactive appearance of the cells. If this variety of tumor was caused by a microörganism, it must be of a nature which requires very favorable conditions for its development.

If a microörganism were considered as the cause of carcinoma, the question as to why it should affect the epithelial cells alone did not seem capable of explanation. Microörganisms could not produce an epithelial or connective tissue-cell; since one being could not form another higher in the animal economy than itself. The action of the microörganism was of an inflammatory character, specific in its nature. In carcinoma the inflammatory changes represented the action of the cellular matrix. The same might be said of sarcoma. The hyperplasia of the matrix was but an indication of the efforts of the tissue to cast out or destroy the foreign body. In conclusion, he remarked that it seemed that to no one theory could be assigned the production of these tumor growths.

DR. J. W. S. GOULEY thought that Dr. McNamara's position concerning the question of microörganisms was well taken, and said it was his belief also that it was not likely that a microörganism could end in an epithelial or any other kind of cell. The cell itself was sufficient to give rise to the mischief which was excited in cases of advanced cancer.

The President, DR. LEALE, remarked that the author of the paper had with a single sharp stroke thrown aside the theory of Darwin, when he stated that one being could not form another higher in the animal economy than itself. He then related a case in which he removed a scirrhus of the breast from a lady, three of whose sisters died of cancer. The family history showed that the father, who was a resident of Richmond, Va., had died of a "tumor of the stomach," the exact nature of which could not be ascertained,

and that the mother had died of a "tumor of the liver." In this patient the cancer did not return in the breast, but three years after the removal of the mammary growth she died of metastatic cancer of the liver; the lungs being also finally implicated. One sister had cauliflower cancer of the uterus, and another scirrhus of the uterus. It was a curious fact that the trained nurse who attended the lady whose breast he removed, also had mammary cancer. One year afterwards he removed this also, and a year after that the axillary glands. It would be of interest, he thought, to know whether it was possible that there could have been a transmission of the affection from one individual to another in these cases.

DR. DANIEL BROWN related a case which he thought might serve to throw some light on the etiology of tumors. A young lady, twenty-two years of age, residing in Eastern Pennsylvania, fell on a doorstep and slightly bruised her hip. Afterward no further effects were noticed for some sixteen or eighteen months, when she began to suffer considerable pain in that part. It was at first supposed that she had rheumatism, but afterward a diagnosis of hip-joint disease was made, and a blister was applied. In a few weeks she became unable to walk, and now a small tumor made its appearance over the femur. This growth gradually increased in size, and it was found to be an osteo-sarcoma. The patient was brought to New York and placed under Dr. Brown's care, and at this time the tumor measured twenty-eight inches in its longest diameter, occupying the whole of the ilium, together with the upper fourth of the femur. The late Dr. James R. Wood saw the case in consultation with Dr. Brown, but it was thought best not to perform an operation. The patient finally died, and the growth was found to weigh between forty and fifty pounds. The chief interest of the case lay in the apparent development of this enormous tumor from so slight a cause.

DR. MCNAMARA said that the occurrence of several cases of cancer in one family as mentioned by Dr. Leale, might be due to predisposing causes, such as climatic influences, etc., to which they are all equally exposed.

DR. FRANK GRAUER presented some pathological specimens for Dr. Janeway, who was unexpectedly prevented from being present. The first case was one of

EPITHELIOMA OF THE ŒSOPHAGUS,

in which there resulted a stricture of the latter, four inches in length. Both recurrent nerves were involved, and, during life, there was paralysis of both vocal cords, neither abduction nor adduction being well performed. Another interesting feature of the case was, that the first symptoms appeared after the patient had swallowed a piece of bone, which, he supposed, had become lodged. Tracheotomy was performed by one of the house physicians of Bellevue Hospital, in order to avert impending suffocation from the laryngeal symptoms. He died, as the result of exhaustion, as he was unable to swallow food, and had great distress in respiration. At the autopsy, there was found dissemination of the cancer in the liver, lungs, and bronchial glands. The main point of interest in connection with the case was, from the comparative rarity of the circumstance, the implication of both recurrent nerves by the pressure of the growth.

The second case, the specimens from which were presented, was one of

PRIMARY TUBERCULOSIS OF THE KIDNEY.

There was pyo-nephritis, and the right ureter was obstructed. The inflammatory process had extended from the kidney to the bladder, which was found to be in a condition of tubercular cystitis.

DR. GOULEY inquired whether there was any history in the latter case.

DR. GRAUER replied that there was not, the patient having been brought into the hospital *in extremis*. Very few tubercles were found in the lungs, and he thought that there could be no doubt that it was a case of primary tuberculosis of the kidney.

DR. GOULEY thought that the question might be raised, whether the tubercular trouble did not commence in the bladder, rather than the kidney. In at least two cases of his own, both of which terminated fatally, such was the case; and in one or two others, the tubercle commenced in the urethra. One of his cases, he had the opportunity of following up for a year. It commenced apparently with a mild cystitis, and this gradually became more aggravated, until the ureter and kidney were involved. The tubercular character of the trouble was not, however, at first, suspected.

DR. GRAUER said in reply that in this case the trouble in the bladder was clearly secondary to that in the kidney, since in the latter the disease was much further advanced than in the bladder; while the ureter was open at its lower extremity, where it enters the bladder, but above, towards the kidney, was occluded.

After the meeting, there was a collation and social reunion in the Library of the New York State Medical Association, in the Carnegie Laboratory.

Recent Literature.

Diseases of the Lungs. By PROF. GERMAIN SÉE, Member of the Academy of Medicine, etc. Translated by E. P. Hurd, M.D., with appendices by George M. Sternberg, M.D., and Prof. Dujardin-Beaumetz. pp. 394. New York: William Wood & Co. 1885.

The author of this work is already well known to his professional brethren as a teacher, practitioner, and writer of eminence; and the present volume may be regarded as one of a series to include, when complete, all the diseases of the lungs. "Bacillary Phthisis" appeared in France in 1884, and in an English translation in 1885; the book under review includes those pulmonary affections of a specific but non-tuberculous nature, and the translator tells us that another volume is in preparation. Our attention is thus limited at present to acute bronchitis, acute pneumonia, gangrene, syphilis, cancer, and hydatids of the lung.

That bronchitis may be a local inflammation due to simple atmospheric action on the bronchial mucous membrane and the skin, Sée believes; he says,[1] "If there still remains a disease which may be rightly attributed to thermal influences, it is assuredly common bronchitis. Till a very recent period, cold was regarded as causative in all inflammations; the microbiological researches of the last few years have assigned to the general dogma of disease *a frigore* its proper place. The more important of these, the pneumonias, the pleurisies, the bronchites, as a whole, even rheumatism,

[1] Page 6.

have passed to the ranks of the infectious diseases; there remains but one acknowledged to be amenable to cold alone, namely common bronchitis, or *rheum* of the air passages." That simple primary pleurisy is an infectious disease is news to us, and we should be glad to hear the evidence in favor of such a view; that there is such a thing as septic pleurisy and that it is a thing far from rare we all know, but Professor Sée seems to class all pleurisies as infectious.

The only form of specific bronchitis systematically discussed is influenza, consideration of the bronchial and broncho-pneumonic inflammation of pertussis, measles, and diphtheria, being reserved for a work on the acute infectious diseases other than those of the lungs. Capillary bronchitis, and broncho- or lobular pneumonia may be the result of the extension of a simple as well as of a specific process starting in the larger tubes.

The nature of pneumonia is then summed up:[2] "It results from these different labors that the experimental demonstration of frank fibrinous pneumonia may be considered as accomplished. This pneumonia may be reproduced in animals, but this reproduction is impossible with ordinary irritant agents. In order that the characteristic lesions may develop, it is necessary that a specific agent, a special microphyte, shall be brought in contact with the pulmonary tissue, and there multiply. Ordinary frank fibrinous pneumonia, then, is an infectious disease, not in the sense of being a general disease, but in the sense of being a parasitic microbic disease. It is an inflammation primarily local, as Grisolle and Andral taught, but it is beside a specific inflammation produced and characterized by a definite microbe. It remains local as long as the parasite does not overpass the limits of the pulmonary parenchyma; it is then simple pneumonia. When it diffuses itself and becomes general, invading the neighboring organs or penetrating the general circulation, whether by way of the lymphatic or blood-vessel, it becomes infectant pneumonia." That the special agent is the ellipsoid coccus Sée is satisfied; to Friedländer's capsule he attaches no importance. To quote another passage:[3] "There is one question, nevertheless, which may be asked, to wit, whether the parasite is the same in all the epidemics of which we have account, or whether with the ordinary parasite there may not be conjoined in certain cases other microphytes? This is an affair for future researches to decide. For the present, and till further enlightened, we may affirm that fibrinous pneumonia, sporadic or epidemic, has always for its essential cause the ellipsoid micrococcus."

The contagiousness of pneumonia also demands further light, though there is increasing probability that it may be contagious.

Here is a short passage which we cannot forbear quoting:[4] "We do not attribute to variation of seasons, the importance which has been assigned to them by Jurgensen and those who have followed him in his way of demonstrating the infectious nature of the disease. If there were no other and better arguments with which to substantiate this theory, it would fall to the ground. Besides, the statistics appealed to as demonstrative, are absolutely puerile, and prove nothing. To one set of statistics, it is always easy to oppose another set."

That pneumonia ever terminates in gangrene Sée doubts seriously, following some of his own countrymen. In these doubts we do not think Sée justified; English, American, and German experience showing clearly that gangrene does occasionally complicate true pneumonia, especially in hard drinkers, though it must be remembered that gangrene is sometimes the primary, solidification of the lungs the secondary, condition.

Chronic induration of the lung may be the outcome of pneumonia, but a termination in caseification, tuberculosis, is characterized as "inadmissible." "Frank fibrinous pneumonia does not end in tuberculization. The facts given as such are mistakes of diagnosis. The inflammation, considered at the outset as fibrinous, was bacillary from the very start. The examination of the sputa does not to-day permit of any doubts in regard to this."[5]

We have thus allowed our author to state some of his more interesting conclusions in his own words. There are other points which we marked for notice, but we have already reached the limits which it is possible for a weekly journal to give to a book notice. There is a good deal of repetition in the book, and more energy as well as space is given to a condemnation of the obsolete treatment, well characterized as "spoliative,"— indiscriminate blood-letting and antimony — than would seem necessary at present. The book is interesting and cannot be read attentively without profit.

The translation is, on the whole, good, but is marred by altogether too many such words as "functionating" "tussigenous," "sectioning," "fermentiferous," "septigenous," and the like. "Debilitation" is found in Worcester, but does not seem to have been used since the time of King Charles. Here and there an error in proof-reading is to be found. F. C. S.

Diseases of the Nose and Throat. By CHARLES E. SAJOUS, M.D., Lecturer on Rhinology and Laryngology, Jefferson Medical School, etc. Illustrated with one hundred chromo-lithographs, from oil paintings by the author, and ninety-three engravings on wood. Philadelphia: F. A. Davis, Attorney, publisher. 1885.

This work is made up of lectures delivered by the author during the spring session of the Jefferson Medical College. We are told in the preface, that it is intended to furnish the general practitioner not only with a guide for the treatment of diseases of the nose and throat, but also to place before him a representation of the normal and diseased parts as they would appear to him were they seen in the living subject.

Ninety-seven of the chromo-lithographs are original. As the author has himself performed the part of artist, we presume he is much better able to judge of color than we are, and that of the plates in this volume, therefore, must pass as accepted. They are certainly well drawn, and the majority of them are very instructive. As a guide to the treatment of the nose and throat, we can cordially recommend this work. The chapters on the instruments used in cleaning and medicating the nasal cavities, pharynx and larynx, and also those on the therapeutics of these regions, set forth the general principles in a useful and practical manner, that will be fully appreciated by general practitioners and students. Specialists will be interested in the volume on account of the originality of the illustrations, and because it is a mirror of the author's own teaching and practice. It is extremely well printed and brought out by the publisher.

Medical and Surgical Journal.

THURSDAY, FEBRUARY 4, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

SEWERAGE AND THE DISPOSAL OF SEWAGE IN POPULOUS PLACES.

A COMMISSION appointed in Massachusetts under a resolve of the Legislature of 1884, has just made its report [1] to the Governor of the Commonwealth on the methods of sewerage and sewage-disposal applicable to various portions of that State, for the relief of certain cities and towns and for the protection of water supplies. Although the investigations were made within rather limited areas and the recommendations have been adapted to the needs of one State, yet the general principles involved are the same everywhere in this country, and the conclusions reached will be of great interest to every community where the proper disposal of filth has become a pressing question.

The commission started with the ground pretty thoroughly prepared for them in the reports of numerous investigations during the last ten years, which have left very little to say, so far as the main conclusions are concerned, as to the methods most practicable under given conditions; and their recommendations agree with previous reports, especially of the State Board of Health. Their ability to spend a large sum of money (nearly the whole of their appropriations of $33,000) and to avail themselves of the services of an accomplished engineer, Mr. Eliot C. Clarke, with a large corps of trained assistants has enabled them to give specific directions, with detailed plans, to meet the requirements of the several cities and towns. From a considerable familiarity with the literature of the subject, we do not hesitate to say that the general report of the commission is the most concise, comprehensive and satisfactory statement of the sewage-question which we have seen; and the appended report of the engineer, beside giving great help to local authorities in settling their problems of drainage, treats the subject in such a broad way as to make his conclusions of practical value throughout the country, while every plan proposed is rendered entirely easy to comprehend by numerous maps admirably drawn and clearly printed. The method adopted, too, is the only correct one, namely, of considering whole river-basins together in drainage schemes, so that the advantage of one town may not be the detriment of another. Mr. Clarke's and the commission's conclusions were submitted to the distinguished engineers, Messrs. Joseph P. Davis, of New York, and Rudolph Hering of Philadelphia, for criticism, revisal and final approval.

The commission's first conclusion is that sewage is of little or no value, but that, although so much diluted as to be valueless, it is not diluted enough to be harmless; that if it can be done effectually and finally it is undoubtedly cheapest and best to cast the foul water entirely away into a body of clean water so large and so free that all trace of the contamination speedily disappears.

Sewage-irrigation they consider admirable if only a number of somewhat intractable conditions can be controlled. Where all things can be made to work together in harmony, it offers a reasonable probability of at least reducing the expense of getting rid of sewage to a minimum. Where an arrangement can be made to operate it in combination with filtration, so that private agriculturists may take the sewage in such quantities and at such times, as they may find it best for their crops, and when not desired can turn it upon filter beds, they think there would be a fair prospect of attaining the largest measure of utilization with the least possible complication and expense. For broad irrigation, pure and simple, the city of Boston, for instance, would need a levelled farm as large as the town of Brookline, upon which two and one-half times the annual rainfall, beside the rain, must be distributed each year, and in wet weather usually to the injury or ruin of most crops — conditions which make the scheme all but impracticable on a large scale.

Intermittent downward filtration is recommended as affording a practicable, economical and efficient means of cleansing sewage, if properly managed, and as having the advantage of being able to filter ten times as much sewage as any crop upon it can profitably absorb. It abandons all idea of profit and simply consists in the application of the maximum quantity of sewage upon the minimum area of land, permitting of only partial utilization, but of more perfect purification. It is susceptible of modification, with a view to partial utilization. It also can be easily and advantageously used in combination with farming enterprise, and is, indeed, an indispensable supplement to broad sewage irrigation.

The climate of Concord and Worcester, Mass., where the sewage of the prison and of the insane asylum is used in irrigation, and at the sewage farm in Pullman, Illinois, is never cold enough for the frost to prevent the flow and absorption of the sewage. The intense heat in summer has not in these places created a nuisance.

Precipitation and depositing processes, chiefly with the aid of lime, involve the disposal of many tons of sludge, a precipitated deposit which cannot be even

[1] Report of a Commission appointed to consider a General System of Drainage, etc. Wright & Potter Printing Company, State Printers, Boston, 1886.

given away, and they do not so completely purify the sewage as to prevent a nuisance if it is cast into clean streams in such quantity as to constitute more than a small per cent. of its volume.

In regard to manufactories, while the commission admit that there is a class of cases where it may be an open question whether it is not for the public interest to abandon a stream or sheet of water to the customary pollution of industry, so long as it does not imperil the public health, they yet say that the public have a right not to be poisoned by the air they breathe any more than by the water they drink, and that there is a foulness which is inadmissible even in a factory stream. Manufacturing refuse, to a certain amount or of a certain kind, may do no harm to a stream, but in many cases the pollution may be so offensive or dangerous as to require a remedy such as the commission think might be brought about by a coöperation of water owners, under the guidance of a board charged with the duty of mitigating the pollution of water-courses.

For the Mystic valley, seventy square miles, with a population of 130,000 to be served, including parts or the whole of Stoneham, Winchester, Woburn, Medford, Belmont, Arlington, Cambridge, Somerville, Melrose, Malden, Everett, Chelsea, Revere and East Boston, an intercepting sewer is recommended to discharge at a point in the southeastern part of Saugus, upon a wide tract of sandy plains for intermittent downward filtration at a cost of $1,520,000 for construction and $20,000 annually for maintenance and renewal. The greater part of the sewage of Cambridge and Somerville is included with the Charles River system, and East Boston has a separate, direct outlet into the harbor.

For the lower or Metropolitan portion of the Charles River valley a main sewer is advised, starting at Waltham, including the Brighton abattoir, uniting with another trunk sewer from Charlestown and the greater portion of Cambridge and Somerville, with their immense hog-slaughtering and rendering establishments, to enter the Boston main-drainage system discharging at Moon Island — a scheme likely to meet with more favor near the present sewer-outlet at Craigie Bridge than in the vicinity of Moon Island, but perhaps admissible. In this way the sewage of forty-six square miles and 180,000 people is provided for at a cost of a little over a million and a half dollars for construction. Milford, Franklin, Wellesley, Marlborough, Westborough and Hopkinton are each recommended to have a separate filtration area for their sewage. The Sudbury and Cochituate basins, including the water-supply of Boston, are provided for by a trunk-sewer for the sewage of the women's prison in Sherborn, South Framingham, Natick, and if necessary, Ashland, with a filtration area for the sewage, in conjunction with which broad irrigation or sewage-farming can be tried, the whole at an estimated cost of $134,843, part of which is to be paid by Boston.

In the lower Neponset basin, Dedham and Hyde Park are temporarily provided for by a plan for a filtration tract between Oakdale and Readville until the time when a main sewer is needed in Dorchester, which they may join and enter the present Boston main drain. In the upper Neponset basin, Sharon, Norwood, Stoughton and Canton, are expected to dispose of their sewage on filtration beds.

The Blackstone River is polluted chiefly by the sewage of Worcester. The remedy suggested is the same as that proposed by the commission appointed by the State Board of Health, Lunacy and Charity, and consists in filtration, with as much sewage-farming as the conditions from time to time admit.

No local sewers are provided for by the plans of the commissioners and none are included in their estimates of cost. The separate system of sewers is recommended for the sewage proper only, on account of the greatly increased cost of providing for street washings and storm-water.

Finally, the commission say, "when we recommend that the prevention of river-pollution be assigned to a board, we do not pretend to prejudge the question whether that Board shall be an existing board or a fresh creation. It seems to us comparatively immaterial, by what instruments our ends are wrought, provided only the work be done economically and speedily and above all, be done well." If an efficient State Board of Health be established this year, as we hope will be the case, the question is worth considering whether it might not perform the duties of a main drainage commission.

FROZEN FRUIT.

FOLLOWING the teachings of the bacteriologists, we have come to look upon cold as a foe to microbic activity, and hence, in a general way, favorable to the interests of public health. But very recently we have been told by the amateur sanitarians of the daily press, of a new peril to life and health, through the action of cold. Frozen oranges, it is said, develop a peculiar virulence through the dissemination throughout their substance of poisonous principles ("acids,") contained in the skin. This theory implies that the skin of an orange naturally contains such a poison, or else that under the action of frost innocent substances take on a poisonous character.

While it is well known that both fruit and rind of the small, bitter Bigarade oranges, or orange berries contain, in the fresh state, a bitter principle called hesperidin, which imparts irritant properties to the essential oil causing in large doses considerable nervous derangement, it is equally well known that the sweet orange peel has a much smaller quantity of hesperidin, enough merely to give it an aromatic and slightly-bitter taste. We have never seen any authority for the belief, that cold has the power to increase the amount of hesperidin, or to form any new chemical compound in the rind of the sweet orange.

This theory of the danger from eating frozen oranges,

was promulgated a fortnight ago or thereabouts, when so large a portion of the Florida crop of oranges was frozen. It is said to have originated with certain planters whose own orchards escaped the frost, but the panic caused by the report was so great, that, far from increasing the price of the unfrozen oranges, as might possibly have been the expectation of its originators, it killed the trade in all Florida oranges, alike. The possibility that fruit might have been frozen, and so have acquired deadly properties, was sufficient to alarm all purchasers.

In this way, a rapidly-growing industry, which would have produced, this year, about a million and a half of boxes of oranges, has been sadly shattered by an idle theory, which purported to be based on scientific grounds, while the proportion of the fruit actually frozen, has probably reached only about twenty-five per cent. of the crop.

Frozen oranges lose their delicacy of flavor, and there is often developed a slightly-bitterish taste, which there is more reason to suppose proceeds from the seeds than from the skins. At least, it is said that Fayal oranges, which have no seeds, and which are quite sour, are made sweeter, and improved in flavor by being frozen. Florida oranges seem to suffer more in flavor from freezing than the fruit from the Mediterranean, and the thicker-skinned and russet varieties of the former are less injured than others.

The great damage resulting from frost, is, of course, the predisposition to decay thus produced. The large amount of fruit seized by the Inspector of Provisions, in Boston last week, and that condemned in New York the week before, was badly decayed, owing to the frozen fruit having been thawed out by the warmth of the steamer, which also hastened decomposition. If the oranges had been thawed slowly, and exposed not too long, they would have been edible and not injurious, though, of course, not a perfect fruit.

It has been the custom of fruit importers in our Northern cities, for years, to sell frozen oranges. It is not uncommon for the outside tiers of boxes in the fruit cargoes of Mediterranean steamers to be touched by frost, on entering port during a cold snap, and occasionally, a sudden fall of the temperature will catch the fruit during its discharge from the vessel, or while it is lying on the wharf. Again, it is liable to be frozen on the westward-bound trains. Such fruit is sold as frozen, and purchasers take their chances on it. They consider it damaged, chiefly because of its liability to decay, but never because the act of freezing has made it poisonous. There is no more reason to fear poisoning from a frozen orange-skin, than from a chilled watermelon, or a glass of iced lemonade.

It is evident, then, that the only proper ground for the condemnation of this fruit is its actual putrefaction, and not the fact of its having been frozen. It seems to us desirable that such matters as the inspection of food, which may involve important and responsible decisions, and in which popular whims may unduly influence on one side or the other the non-expert layman, should be directly under charge of our local Boards of Health. As it is, in Boston, the Board of Health has nothing to do with such seizures, which are in the province of the Inspector of Provisions, who is appointed by, and is responsible directly to the mayor. The owner of seized articles has the privilege by law of appealing from the officer's judgment to that of the Board of Health, whose decision, in that case, is final. There might be less chance of injustice being done to commercial interests by pseudo-science, while the welfare of the public would be equally well guarded, if the original jurisdiction, in such matters, lay with the Board of Health.

RAW MEAT AND MEAT POWDERS.

IN that *a culinary* period of the world's history, which Charles Lamb, in his famous "Dissertation on Roast Pig," calls the "Cho-fang, or Cook's Holiday," before Hoti and Bobo, by the accident of the burning of their hut, in which a litter of pigs was consumed, first learned the savory delights of roast meat, the human race was hardy, and sickness was unknown; it was the golden age, so says the legend. Primitive man may have had his surfeits and his bradypopsias; he was hardly, however, the puny, neuropathic, debilitated individual which the art of cookery, and the refinements of civilization have made of his modern descendant.

Raw meat was introduced into *therapeutics* by Weisse, of St. Petersburg, and has proved an aliment of the utmost restorative utility, not only in affections of the stomach and intestines (its good effects are witnessed, especially, in acute intestinal catarrh), but also, in chronic wasting diseases, generally, among which we may particularize pulmonary phthisis. The facility of digestion of this kind of pabulum, when administered in the form of pulp, and laten dripping with its sanguineous juices, is a matter of common notoriety.

The anæmic and debilitated speedily experience hæmatic recuperation and re-invigoration. This easily assimilable diet has worked wonders in restoration, where iron and cod liver oil have failed. Dyspeptics, whose irritable stomachs would bear nothing else, have tolerated the raw-meat regimen, and life has been prolonged with comfort, where cure was impossible; even infantile therapeutics has profited by it.

It cannot, however, be said that this kind of food is palatable, attractive, or altogether free from the danger of tænia; it must be, moreover, admitted, that that delicious aroma and savor, which, in Lamb's dissertation first awakened desire in the primitive raw-meat devourer for roast pig, are important factors in normal ingestion and digestion.

Hence, it is, that of all the recent additions to therapeutics, meat powders deserve a pre-eminent place. Such preparations, representing the entire substance and juices of animal muscle (and some of them are artificially peptonized), are handy, of great sanitary value, and enhance incalculably the resources of the modern

physician. Nor need the latter, if he be an ardent protectionist, any longer patronize the venders of foreign extracts (even though these have the brand of the illustrious Liebeg); let him wait patiently and the polite representative of the home manufacturer will generously bring him just the article he wants — a delicate little can, containing (well freighted with fragrant osmazome) the proteids of a whole Texas steer.

A PROPOSED BUREAU OF PUBLIC HEALTH AT WASHINGTON.

A BILL has been presented in the National House of Representatives and referred to the Committee on Commerce, for the purpose of creating a Bureau of Public Health in the Department of the Interior.

Provision is made in the bill for the investigation of contagious and epidemic diseases; for the obtaining of information as to the sanitary condition of foreign ports; the collection of statistics of mortality, and pervalence of disease in all portions of the country; and the publication of all the information thus obtained in a weekly bulletin and annual report.

It appears to have been thought necessary to establish an office without quarantine powers and without the patronage which proved so unfortunate a burden to the National Board of Health.

A Bureau so organized would have the very important advantage of a close connection with a great department of government already controlling services of a scientific character and able to protect them against the Treasury Department even.

The old Board of Health seems to be so utterly out of favor that its resurrection or any attempt at the formation of a new Board would be predestined to certain defeat.

MEDICAL NOTES.

— Dr. Crichton Brown, of London, has received the honor of knighthood.

— At the annual meeting of the New Haven Medical Association, held January 4th, officers were elected as follows: President, Dr. W. O. Ayres; first vice-president, Dr. Henry Fleischner; second vice-president, Dr. W. H. Carmalt; secretary and treasurer, Dr. Gustavus Eliot; prudential committee, Dr. M. C. O'Connor and Dr. Henry Pierpont: finance committee, Dr. F. L. Dibble and Dr. C. A. Lindsley.

— Dr. Piffard has retired from his editorial connection with the *Journal of Cutaneous and Venereal Diseases*. The journal will be continued under the sole editorial charge of Dr. P. A. Morrow. We may remind our readers that this is the only publication in the English language devoted to skin and venereal diseases, and during the three years of its existence, it has won for itself a high reputation for scientific excellence as well as practical utility.

— The story comes from Lowell of a disciple of Pasteur, who being troubled with dyspepsia, is inoculating Welsh rarebits before he eats them.

— The proposed engagement of the returned Pasteur-hydrophobia-inoculated Newark children by a Dime Museum, and the report of overtures made by the latter to M. Pasteur and Dr. Billings to join in the show, seems a natural conclusion to the international episode which has monopolized so much attention in recent weeks.

— A sensible suggestion is made by two of Maine's executive councillors who were upon a visiting committee to the insane hospital, that some method should be devised to separate the insane criminals from other inmates of the hospital. They remark that it seems unjust that the innocent and unfortunate insane should be confined with murderers and other criminals, who are sent to the hospital to be watched and have their condition studied. There are now twenty-eight criminals in the hospital.

— Herr Oppler has ascertained by experiments, says the *London Medical Record*, that roasted coffee acts on iodoform as an active deodorizer. As roasted coffee is a powerful disinfectant, it has, in combination with iodoform, an excellent influence in promoting cicatrization. Herr Oppler recommends the following formulæ: Iodoform (pure), 50 grammes; roasted coffee in very fine powder, 25 grammes; a few drops of spirits of ether; or iodoform (pure), 2 grammes; paraffin, 10 grammes; roasted coffee in fine powder, 0.3 gramme.

BOSTON.

— A fatal case of glanders in a hostler who took care of a horse suffering from the disease was reported last week.

— Dr. Charles G. Weld has given $500 toward establishing a library for the nurses at the Boston City Hospital. Dr. Weld was formerly a house officer at the hospital.

— Dr. Pliny Earle, the retiring superintendent of the State Lunatic Hospital, at Northampton, has a unique scrap-book in which he has preserved two hundred different envelopes received during his administration, spelling his name in as many different ways.

— A measure supported by voluminous petitions is before the Committee of the Massachusetts Legislature on Public Health, to restrict the sale of tobacco to minors under the age of fifteen or sixteen years. It is claimed by the petitioners that both boys and girls in the public schools are addicted to the use of cigarettes to an alarming degree.

— About two hundred invitations were sent out, lately, by the Trustees of the Boston City Hospital, to an informal inspection, on the evening of January 29th, of the new Nurses' Home, at the corner of Springfield Street and Harrison Avenue. Much satisfaction was expressed by those who visited the building, at the arrangements and accommodations.

— The Inspector of Provisions recently seized and condemned a considerable portion of the fruit cargo of one of the Savannah steamers.

— The new Hospital, at Cambridge, has been completed, at a cost of from sixty to sixty-five thousand dollars. It will be opened for use very shortly.

— The officers of the Hospital Newspaper Society have made public a letter which says: "The society has sent 294 books, 7,611 magazines and large numbers of illustrated papers to the following named places: Tewksbury, two insane asylums at Worcester, Palmer, Bridgewater, Danvers Insane Asylum, Deer Island, Rainsford Island, the Life-Saving Station, lighthouses, North Bennet street, Reformatory at Concord, Lancaster Industrial School for Girls. The society wishes to thank the persons who have kindly dropped their daily papers into the boxes in the railroad stations. The boxes have never been so full, and we have received during the year 200,000 papers. These boxes are emptied every morning, the contents being distributed among the City Hospital, Deer and Rainsford islands. The Chaplain writes that the 'old men at Rainsford look and talk more cheerfully since they have had the daily papers.' At Christmas the society sent six thousand Christmas cards to different institutions. We want more books, magazines and illustrated papers. We can find a home for every sort of book; what cannot be disposed of here will be welcomed in the West. For this work we require $300, and for so small an outlay it gives a great deal of pleasure. Christmas cards, books and papers may be sent to 113 Revere street; contributions and subscriptions to Mrs. Hartman Kuhn, 64 Beacon street."

NEW YORK.

— The trial of Gen. Alexander Shaler, President of the Board of Health, arraigned on a charge of bribery, in the selection of sites for armories for the city, came off on the 26th and 27th of January, before Judge Barrett, in the Court of Oyer and Terminer; but the jury being unable to agree, a new trial will have to be held at the next term of the Court, which begins February 15th. The jury stood ten for conviction, and two for acquittal.

— At a special meeting of the Dutchess County Medical Society, held at Poughkeepsie, January 27th, charges were preferred against Dr. Samuel Wimpleberg, for violation of the code of ethics, in inserting an advertisement in the *Delaware Times*, calling the attention of the public to the fact that he made eye and ear troubles a specialty, the advertisement being accompanied by printed cuts of an eye and ear. The Comitia Minora made a report, recommending the expulsion of the offending member; but, after considerable discussion, the Society rejected the Comitia's report by a vote of fourteen to five. It was the opinion of the majority that, while Dr. Wimpleberg's act was "derogatory to the dignity of the profession," under the law of the State, a member could be expelled only for "gross ignorance, malpractice, and immorality."

Miscellany.

THE TREATMENT OF CARBUNCLE.

Dr. James Collins writes in the *Philadelphia Medical News:* I have lately treated two cases of carbuncle on the back of the neck by a method which seems to have some advantages. The patient is put under the influence of an anæsthetic, and a linear incision made. I then take a scoop and remove all the necrosed tissue, and wash the parts thoroughly with an antiseptic solution of mercuric chloride. I then put in a drainage-tube, and insert two stitches to bring the two central parts together. Each day the cavity is thoroughly washed out with the antiseptic solution. The patients have done well, and the cicatrix has been less than after any other method I have tried. The success depends upon the removal of the necrosed tissue and the use of the antiseptic solution.

SUDDEN DEATH FROM ŒDEMA OF THE GLOTTIS.

Dr. W. J. Jones, of Baltimore, reports in the Philadelphia *Medical Times* (Oct. 3,) the following case, which serves to show the clinical significance and pathological condition of œdema of the glottis:—

J. B., colored, male, æt. fifty-two years, was admitted into the hospital at Bay View Asylum on the 24th of May last. He gave a history of having been a hard-working laboring-man, and the duties of his vocation often subjected him to considerable exposure. He was addicted to drinking a little too freely of alcohol at times, though not a constant drinker. He denied the history of any venereal disease. A careful physical examination of the patient showed that he was a large, well-built man. He gave no evidence of any disease of his lungs or heart. There was slight œdema of his lower extremities, which was not constant. An examination of his urine showed the presence of albumen and casts, and accordingly a diagnosis of morbus Brightii was made. Infus. digitalis was administered in ℥ss doses thrice daily, and under its influence he seemed to improve until the morning of June 4, when, upon making my rounds of the hospital about ten o'clock, he complained of sore throat, inability to swallow easily, and slight dyspnœa. His lungs were examined, and air was found to enter freely. There was nothing to be seen in his throat to give alarm, though there was some slight swelling and redness about the fauces and the mucous membrane of the pharynx. The epiglottis, likewise, was red and thickened to some extent. Having no evidence at this time to lead me to suspect the fatal termination which so soon followed, I prescribed a simple gargle of potassii chloras, tinct. ferri chlor., glycerin and water, and left him, promising to return again within an hour and make a more thorough examination into his condition. I was about to return to him at the time stated, when a messenger met me with the information that my patient was dead. An autopsy made a few hours after death showed the mucous membrane of the epiglottis and the entire larynx to be very much swollen and œdematous. The œdema reached to such a high degree as almost to occlude the entrance into the larynx. In the pharynx and on the posterior part of the tongue, the follicles were somewhat enlarged; both lungs slightly adherent to the pleura at various places, other-

wise normal; heart somewhat enlarged; left ventricle relaxed and dilated to some extent, valves soft; liver of ordinary size, and pale; spleen normal; kidneys of ordinary size, their capsules slightly adherent in places; the parenchyma hyperæmic.

The case is an important one from the fact of its rapid fatal termination and as to its cause. The suddenness with which the trouble began and the rapidity of its progress must be referred to one of the several causes of œdema of the glottis; and as the patient gave evidence both clinically and pathologically of morbus Brightii, and as œdema of the glottis may occur as the first and only dropsical affection connected with disease of the kidney, as stated by Flint, it is more than probable that the patient's kidney-disease was the prime factor in bringing about the cause which so suddenly terminated his life.

CONCEPTION AFTER CURETTING OF THE UTERUS.[1]

IT has been made an objection to curetting of the uterus, that thereby, conception is rendered difficult, if not impossible (B. Schultze). Düvelius has reported sixty cases where, after curetting, conception did ensue, yet, in the discussion of his paper, no others were familiar with similar cases. Benicke has, therefore, carefully gone over his records, and is able to report ten cases where conception followed on curetting. Of these ten cases, the operation was undertaken once for the cure of endometritis hæmorrhagica, and in nine, for the removal of retained membrane. In three of the cases, the operation was repeated, so that altogether, it was performed thirteen times. In five of the cases, the conception ended prematurely, but this was not a result of the curetting, seeing that the patients had the habit of aborting. In two of those cases, conception ensued four or five weeks, respectively, after curetting; in the others, two and a half, three, four and a half, up to seventeen months after. Benicke's conclusion is that the fear lest curetting should interfere with further conception is absolutely groundless; indeed, that in many cases, it is an excellent method of preparing the endometrium for a new conception.

AN OLD ANATOMICAL PREPARATION.

PROFESSOR ROTH, of Basle, has recently been engaged, we learn from the *Lancet*, in investigating the history of a remarkable relic which the University of Basle possesses. It is a skeleton prepared by the founder of anatomy, Andreas Vesalius, and as it bears the date 1543, it may be justly regarded as the oldest anatomical preparation in existence. Professor Roth has published a pamphlet upon the relations of Vesalius with the old Swiss town, from which it appears, contrary to previous ideas, that the great anatomist only once took up his residence in Basle — namely, in 1543, when he came from Padua for the specific purpose of seeing his great work, "De Humani Corporis Fabrica," through the press of Jo. Oporinus, and that, during that visit, he undertook no official teaching. The dissection of the human body was, at that time, most reluctantly allowed by the authorities, and it was only occasionally that the body of a criminal was sent to the medical schools, such a concession having, previously to 1543, happened only once in Basle, namely, in 1531; and one may imagine the intense longing for such an opportunity on the part of the University students and professors, to occur whilst Vesalius was with them. Their desire was gratified. On the 12th of May in that year, one Jacob Karer was beheaded for a murderous assault upon his wife, and the body was handed over to the University, to be dissected by Vesalius. On the afternoon of that day, and for many days afterwards, the great master taught to students and teachers, a new anatomy; and when the dissection was completed, he prepared the skeleton, and with his wonted generosity, presented it to the University — a gift, in those days, of no trifling value — where, to this day, it remains, in the words of the inscription, "Artis et industriæ suæ specimen." As the possessor of the only known relic of the greatest of human anatomists, the University may well be proud of its treasure.

THE ACTION OF THE MIDDLESEX NORTH DISTRICT MEDICAL SOCIETY ON THE DEATH OF DR. JOHN O. GREEN.

AT a recent meeting of the Middlesex North District Medical Society, the President, Dr. Wm. Bass, in the chair, Dr. F. Nickerson, for the committee appointed to take action on the death of Dr. John O. Green, reported the following:

Your committee recommend that the following comments on the life of Dr. Green be accepted as the sense of this society:

Under the shadow of sorrow which has fallen upon us in the death of an honored associate, Dr. John Orne Green, we pay the worthiest tribute to his memory and do the best service living by setting forth some, at least, of the salutary lessons bequeathed by his exemplary life.

The career of Dr. Green, covering a period of eighty-six years and including a residence and medical practice of sixty-three years in this community, is so interwoven with the events in which he bore a part as to be almost as much a subject of history as of biography.

His birthplace was Malden, Mass., his father was the Rev. Aaron Green, and he was named after his maternal uncle, John Orne, of Lynnfield, Mass. He received his early education in the schools of his native town, and his preparatory training for college at the academy of Dr. Homans in Medford, Mass. He entered Harvard University, as a freshman, at the age of fourteen years, and graduated with honors in the class of 1817, which numbered sixty-seven men, among them George Bancroft, Caleb Cushing, Rev. Dr. Tyng and President Alva Woods. During his college course he paid particular attention to theological studies, with the design of entering the ministry, but afterwards abandoned this idea. After his graduation he acted for one year as principal of a Latin school at Castine, Maine. He then entered the office of Dr. Edward Reynolds, of Boston, under whom and with the late Dr. Winslow Lewis as a fellow student, he availed himself of the excellent clinical advantages offered at the almshouse on Leverett street. He attended lectures at the Harvard Medical school, from which institution he received the degree of M.D., in 1822.

Coming to Lowell, an entire stranger, when the place contained only 200 inhabitants, and when the stakes which marked out the site of the future city had just been planted, he hewed his way, by his integrity, intelligence and persevering industry, into the high position which he always held as a gentleman, a citizen and a physician.

The name of Green is associated with that of Colburn and of Edson in the early struggle for educational reform, which, maintained with courage and persistency, against a fierce opposition, laid the foundation of the present public school system of this city. The heroic labors of these men

are commemorated in the school structures which bear their names. In 1870, Dr. Green delivered the address at the dedication of the new Green school which took the place of the old building on Middle street.

Dr. Green was also prominently connected with the introduction into Lowell of lyceum courses of lectures, to which he himself contributed one or more essays.

He had no ambition for public office and despised the puerilities and trickeries of politics. He was a member of the school board for fifteen years and for nine years was its chairman and wrote its reports. He served also as an alderman, and as health commissioner, he, for seven years, prepared the municipal bills of mortality which preceded the present system of registration. He was formerly a councillor of the Massachusetts Medical society, and in 1846 delivered the annual address before that body on "The Factory System in its Hygienic Relations."

Born and reared to manhood on the spot where the Revolutionary patriot, the Rev. Peter Thacher, had lived and viewed the battle of Bunker Hill, he early caught the historic spirit which impressed itself on his literary pursuits and professional methods and found public expression in papers on historical subjects.

While his energies were habitually taxed by the motley duties which appertain to that medical factotum, the general practitioner, his mind had a more special bent for pathology. Methodical in all his ways, he kept careful and instructive records of the autopsies in which he had been engaged. In the *American Journal of Medical Sciences* for July, 1834, he reported two cases of fracture of the liver, which were republished in Germany. In the *Boston Medical and Surgical Journal*, for December, 1837, he wrote an account of an epidemic of small-pox in Lowell. He also rendered valuable aid, by his investigations, to Dr. Elisha Bartlett, in his work on fevers, the second edition of which was dedicated to him.

The earnestness with which he consecrated himself to the cause of Christianity received its first impetus from the home of his childhood, the country parsonage; to the sanctifying and refining influences of the parental instruction imparted and the society enjoyed there, he ever recurred with the most profound sentiments of reverence and affection. The spirit which pervaded his religious views, inspired his conduct and made it the very soul of professional honor, is best illustrated by his own words, which are to be found in his address on the life and character of Dr. Dalton: "Accustomed to the most constant expression of their most intimate feelings in words, there are those who lose sight of the fact that there is a religion no less pure than their own which shrinks from such constant assertion of itself, and which is satisfied to do justly, love mercy, and walk humbly with God."

The last years of Dr. Green's life were full of activity. To this fact his efficiency as a member of the staff of St. John's hospital and president of the Lowell Old Resident's Association, bears ample testimony. Performing his professional labors almost uninterruptedly till within a short time before his death, he at last yielded to the infirmities of advanced age, and after an illness of a few months, on the 23d of December, 1885, he serenely closed his eyes on earthly scenes.

Thus ended a life whose service was eminently that of God and humanity, and whose watchwords were truth and faithfulness to duty.

The report of the committee was unanimously adopted by a rising vote.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 23, 1886.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Scarlet Fever.	Typhoid Fever.	Diphtheria and Croup.

Deaths reported 1,865: under five years of age 639; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 292, consumption 319, lung diseases 280, diphtheria and croup 139, scarlet fever 30, typhoid fever 28, malarial fever 23, diarrhœal diseases 27, whooping-cough 22, cerebro-spinal meningitis 11, measles six, erysipelas three, puerperal fever two, small-pox one. From diarrhœal diseases, New Orleans seven, New York six, Philadelphia four, Boston and Providence three each, Lowell, Fall River, New Bedford and Salem one each. From malarial fever, New York 14, New Orleans five, Baltimore four. From whooping-cough, New York 16, Philadelphia and Baltimore two each, Providence and Fall River one each. From cerebro-spinal meningitis, New York five, Boston, Worcester, Fall River, Holyoke, Taunton and Malden one each. From measles, New York and Philadelphia two each, Baltimore and Providence one each. From erysipelas, Boston two, Baltimore one. From puerperal fever, Boston and Nashville one each. From small-pox New York one.

In 111 cities and towns of Massachusetts, with a population of 1,311,869 (population of the State 1,941,465), the total death-rate for the week was 18.23 against 17.16 and 16.98 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,909,817, for the week ending January 9th the death-rate was 22.5. Deaths reported 3,927: infants under one year of age 898; whooping-cough 174, measles 113, fever 42, diarrhœa 41, scarlet fever 38, diphtheria 37, small-pox (Liverpool, two, Nottingham one), three.

The death-rates ranged from 18.5 in Sheffield to 30.8 in Bolton; Birkenhead 24.0; Birmingham 21.0; Bradford 20.2; Huddersfield 28.3; Hull 19.6; Leeds 19.2; Liverpool 24.2; London 22.4; Manchester 28.2; Nottingham 27.8.

In Edinburgh 16.2; Glasgow 28.8; Dublin 28.8.

The meteorological record for week ending January 23, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Jan. 23, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 23, 1886, TO JANUARY 29, 1886.

SUMMERS, JOHN E., colonel and surgeon, U. S. Army. Retired from active service, by operation of law, January 24, 1886. S. O. 20, A. G. O., January 25, 1886.

WATERS, WM. E., major and surgeon. Granted leave of absence for twelve months and fifteen days. S. O. 5, Division of the Atlantic, January 23, 1886.

BANISTER, J. M., assistant surgeon. Ordered for temporary duty at Fort Warren, Mass. S. O. 16, Department East, January 25, 1885.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, February 10th, at 7.45 o'clock. Papers: Dr. W. B. Mackie, "A Case of Typhoid Fever complicated by Intestinal Hæmorrhage, Embolism of Femoral Artery and Gangrene of the Foot." Dr. C. E. Wing, of Jamaica Plain, "A Summer Ramble through North Carolina."

F. I. KNIGHT, M.D., *Chairman.*

ALBERT N. BLODGETT, *Secretary*, 138 Boylston St.

ERRATA.

In Dr. Stedman's report on Progress, issue of the 28th of January, page 81, second column, line 16, from the bottom, for "their" read "the"; page 81, second column, the clause beginning on line 10 from bottom should read: "No other form of insanity is so prolific of accidents." Page 83, line 26, for "and" read "was"; page 83, line 40, for "intestinal" read "interstitial."

DEATH.

Samuel Hutchins, M.D., of Danielsonville, Conn., died on January 16th, of augina pectoris at the age of sixty-seven years. He leaves a widow and four daughters.

BOOKS AND PAMPHLETS RECEIVED.

Fractures and Dislocations. By T. Pickering Pick, F.R.C.S., Surgeon to St. George's Hospital, etc. Revised, with 93 Engravings. Philadelphia: Lea Brothers & Co. 1886.

THE ADVISABILITY OF INDUCING ABORTION IN CASES OF SO-CALLED UNCONTROLLABLE VOMITING OF PREGNANCY.[1]

BY O. W. DOE, M.D.

THE rarity of this disease naturally prevents one from deducing principles on which to base his method of practice from his own experience. This is especially so with me, as I have seen only one indisputable case during the past twelve years.

Consequently in this paper my deductions are drawn from a compilation of all the undoubted cases that could be found referred to in the Index Medicus and various works on obstetrics.

In looking up the various references I want to publicly acknowledge my great indebtedness to Dr. S. H. Ayer, for the very valuable assistance he has given me.

At a recent meeting of the Boston Obstetrical Society I reported a case of so-called uncontrollable vomiting of pregnancy, which was relieved by changing the malposition of the uterus after almost every remedial agent had been unsuccessfully tried and the patient's condition had become most alarming.

In consultation, the question of inducing abortion arose and it was certainly a most difficult and anxious one to decide. The patient had taken no nourishment by the mouth for nearly five weeks, as even the mention of food would excite vomiting. During this time she had been fed by nutritive enemata. Nausea was constant and intense, and vomiting of a thin yellowish fluid, sometimes half a cupful at a time, occurred every two or three hours. Any sudden noise, or sudden appearance of one by the bedside would excite vomiting.

Notwithstanding the fact that the enemata had been well born, the patient had become greatly emaciated and too weak to move herself in bed.

There was excessive ptyalism, coming on more frequently at night; at other times thirst was intense, tongue parched and dry, breath very offensive, and, along the course of the œsophagus and at the epigastrium, was marked tenderness. Pulse 116, temperature 97°.

The cervix was firm and unyielding; the os only slightly patulous. The uterus was markedly anteverted, the fundus resting against the rami of the pubes, and, on examination, could be raised up out of the cavity of the pelvis, but fell back again directly upon the removal of the finger. She was within three or four days, as near as could be determined, of being three months advanced. Taking into consideration the unyielding and firm condition of the cervix, I reasoned that were abortion to be induced she was far too weak to bear the shock necessarily attending it, and even if she happily withstood this there was the probability of hæmorrhage, which, in one so weak, would at its very outset prove fatal. Furthermore, should she surmount even these two dangers, there still remained a third, namely, septicæmia, which one would almost expect to follow in a person so reduced when abortion was artificially and forcibly produced. In favor of delay and trusting to other means was the fact that in her preceding pregnancy the nausea and vomiting though much less severe, yielded suddenly and completely at the beginning of the fourth month after the attending physician had, on vaginal examination, by chance raised the uterus high up out of the cavity of the pelvis. Furthermore, there was no continued irritability of the bowels, so that, as a rule, the enemata were well retained. Had at this time from any cause rectal alimentation been impracticable, and the elevation of the uterus and retention by vaginal support proved inefficient, even in the face of every threatening danger, I should have advised rapid abortion under ether and full hypodermic stimulation. Should the result have proved fatal, I should have considered that the error in treatment ought to be referred to the delay, rather than to the method employed.

The exciting cause of the vomiting in this case seemed to be wholly the displacement of the uterus and consequent pressure upon the pelvic parts. As soon as the pressure was permanently removed, by raising the body of the uterus out of the pelvic cavity, the vomiting and nausea instantly ceased. A peculiar feature illustrating the principle of cause and effect here was that as soon as the vaginal tampons were at all displaced, so as to allow the body to prolapse or antevert, the nausea and vomiting would directly return. Looking back upon this case and noting each stage of the disease as it unfolded itself, and remembering how inefficient all therapeutic agents proved, I should be inclined to follow in another case a course of treatment like the following: rectal alimentation combined with chloral and bromide as soon as the vomiting became pronounced; careful examination to detect any malposition of the uterus and as soon as observed to remedy it by the use of a proper pessary and with the tamponing of the vagina with the object of raising the body as far out of the pelvis as possible. Should no relief follow soon after the beginning of the fourth month, or if even earlier no relief followed the correction of the displacement, and the patient's strength was rapidly diminishing, or if rectal irritation became continuous, I should unhesitatingly induce abortion. Or, more concisely, impracticable rectal alimentation combined with continuous vomiting, wholly unrelieved by correcting any existing uterine displacement, attended with rapid pulse, offensive breath, subnormal temperature and marked increasing prostration would hereafter decide me to induce abortion at whatever the period of pregnancy might be.

Under the conditions I have just expressed there is no doubt in my mind as to the advisability of inducing abortion in cases of so-called uncontrollable vomiting of pregnancy, still it will be but fair to present to you the various differences of opinion upon the subject. Every physician has probably either seen or read of cases of death from this terrible complication of pregnancy, and yet many eminent practitioners say that abortion without exception is entirely unnecessary. Dr. Mortimer H. Jordan, of Birmingham, Ala., says:[2] "Among other eminent men I will mention Cazeaux, Burns, Dubois, Desermaux, Carl Braun, of Vienna, and Henry F. Campbell, of Augusta, Ga., who state that artificial production of abortion is never justifiable for gravid nausea." Dr. Campbell says: "That under the careful and systematic application of rectal alimentation artificial abortion for the relief of gravid nausea can be banished from practice even as a last resort." On the other hand, I quote from Dr. Davenport as follows:[3] "Denman, Merriman, Burns,

[1] Read before the Obstetrical Section of the Suffolk District Medical Society, December 16, 1885.

[2] Trans. of the Med. Assoc. of the State of Alabama, 1883.

[3] Trans. Vermont Med. Soc., 1878, St. Albans, 1879, p. 39, 40.

Davis, Lee, Ashwell, Blundell, Churchill and Condie all advocate the induction of premature labor, without reference to the period of gestation; if the symptoms and condition of the patient demand it, then it is to be done." J. Marion Sims writes as follows:[4] "During my residence in Paris some years ago, I saw two deaths from pregnancy-vomiting, and I saw two cases that were snatched from the jaws of death by the induction of abortion. Professor Trousseau and Dr. Johnston of Paris were consulted in these cases and both agreed that prompt abortion was the only means of saving life." Dr. Murphy sums up four cases as follows:[5] "Thus in four cases of excessive vomiting followed by exhaustion, three were lost through hesitation and delay; and one was saved by promptitude in inducing miscarriage."

Lusk says:[6] "When the vomiting is literally uncontrollable, a rare event where the physician commands the full coöperation of his patient, and death from starvation threatens, there remains as an ultimate resource the artificial induction of abortion or premature labor.

Dr. Scott says:[7] "It is criminal to allow a patient to go to the last extremity before an effort is made to produce an effect which we know is certain to relieve her and preserve a life which is the 'right of woman.'" On the other hand, however, cases are recorded where the patient sank steadily and in which life had been despaired of by the physician in charge, and in which abortion had been refused by the patient, and yet upon the exhibition of some new remedy, a change for the better has appeared and a steady gain made from that time on. P. Dubois[8] speaks of a case which illustrates this point, it being one which had been abandoned by himself and colleague and which afterward promptly recovered on the exhibition of a purgative.

Dr. Engelmann says:[9] "Of course abortion is to be induced as a last remedy, but it is always to be used in time, and as soon as it is found that all others fail." The principal fact is, practitioners wait too long. Dr. Coles says:[10] "I have never had a case in my own practice where the induction of labor was necessary, but I have seen two cases where this had to be resorted to. In these cases the women were *in extremis;* one of them died notwithstanding the abortion. She had gone too far. We had waited too long for this spontaneous change."

Leishman says:[11] "The conclusion at which Cazeaux and others have arrived is that under no circumstances are we justified in inducing premature labor for the relief of vomiting of pregnancy." Cazeaux reports seven cases of induced abortion with six deaths. According to his estimate, one in seven is the average of escapes from death after the operation (induced abortion). He thinks the most desperate cases, as he cites several to show, have a better chance on the expectant plan, with such nutriments as can be retained, than in the resort to induced abortion.

Out of 118 cases collected by Gueniot there were 72 recoveries and 46 deaths, represented as follows:

	Recoveries.	Deaths.
Without abortion in very severe cases after diversified treatment	31	28
Following spontaneous abortion also in very severe cases	20	7
After abortion or induced labor in cases more or less desperate	21	11
Total,	72	46

Dr. Alfred McClintock in a paper before the Dublin Obstetrical Society read in 1873, reported 36 cases in which abortion was induced with 27 recoveries and nine deaths.

In selecting the following 48 cases, which I am about to report, there was considerable difficulty experienced in deciding whether a case should be truly called "uncontrollable" in the popular sense of the word, or simply obstinate. It is evident, however, that all cases in which death occurred without artificial abortion were certainly uncontrollable, and that by adding to the list of recoveries, cases which were more or less doubtful, the percentage of deaths became correspondingly less.

All of the cases are very briefly reported, some from necessity, others from choice, the idea being not to bring forward a full and complete report of each case, but simply to place before you such points as have a direct bearing on the subject of this paper. I think, however, the principal point to be brought out is clearly shown; namely, that after the emptying of the uterus, whether artificially or otherwise, the vomiting, with very few exceptions, soon ceased, and that in nearly all cases recovery took place, a fatal termination occurring in those in which interference had been too long deferred.

I shall first present to you twenty-eight cases of uncontrollable vomiting, in which artificial abortion was not induced, after which I shall read twenty cases which were terminated by artificial abortion.

TWENTY-EIGHT CASES OF UNCONTROLLABLE VOMITING OF PREGNANCY, IN WHICH ARTIFICIAL ABORTION WAS NOT INDUCED.

No.	Reported by.	Age.	Multip. or Primip.	Vomiting. Began.	Vomiting. Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
1	F. Minot, M.D. Boston, Mass.	Young.	M_2	8th week.	20th wk.	Nutritive enemata.	Recov.	Vomiting was soon accompanied by excessive salivation. "Pulse gradually rose to upwards of 130 in the minute." There was "much emaciation, prostration, loss of sleep, and depression of spirits." "Any excitement, even an accidental loud noise in the room would cause urgent retching and rejection of anything that happened to be in the stomach." Quickening May 22; permanent relief June 1.	Boston Medical and Surgical Journal 1880, cii. p. 302.

TWENTY-EIGHT CASES OF UNCONTROLLABLE VOMITING, IN WHICH ARTIFICIAL ABORTION WAS NOT INDUCED. *(Continued.)*

No.	Reported by.	Age.	Multip. or Primip.	Vomiting. Began.	Vomiting. Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
2	E. Copeman, M.D.	25	P	6th mo.	?	Internal remedies failed. Rectal alimentation for 3 weeks. Cervix dilated (Copeman's method).	Recov.	"Vomiting and retching became almost incessant." Vaginal examination found posterior lip of cervix hard and unyielding. "Effect (Copeman's method) was instantaneous, the stomach retaining the first thing administered."	British M. J., Lond., 1879, 1, 736.
3	J. Farrant Fry, M. D., Swansea.	?	M_6	6th week.	8th week.	Internal treatment failed. Cervix dilated (Copeman's method).	Recov.	The effect (Copeman's method) was almost immediate; food was retained and patient quickly regained strength. Went to term.	British M. J., Lond., 1880, 1, p. 399.
4	J. F. Baldwin, M.D., Columbus, Ohio.	29	P	6th week.	10th wk.	Internal remedies with failure. Cervix dilated (Copeman's method).	Recov.	"Nitrate of silver to erosion, gave no relief." After dilatation of cervix "all vomiting ceased as by magic."	Ohio Medical Record, Columbus, 1879, 1880, iv., p. 198-200.
5	F. W. Lester, M.D., Key West, Fla.	30	M	Almost from time of conception.	14th wk.	Internal treatment failed. Ether to pneumo-gastric nerves under sterno mastoids, alternately.	Recov.	For four weeks previous to ether treatment, patient vomited every few moments. Ether was applied every two hours the first day for ten minutes at a time. In three days vomiting ceased entirely.	Med. Record, N. Y., 1880, xviii. 474.
6	Jesse Crounse, M. D., Knowersville.	34	M_4	Soon after conception.	After 6th month.	Internal remedies failed. Moral treatment: slight irritation of os, pretending attempted abortion which patient desired. "Each remedy was in turn given a trial and still no improvement, but on the contrary I saw her wasting and becoming more feeble every day."	Recov.	With first child suffered from nausea and vomiting for seven and one-half months. In second pregnancy, labor was induced at three and one-half months, successfully. In third, labor was again induced at third month without any trouble. In this case, patient begged physician to induce labor, and finally he consented. He, however, merely irritated os with a probe, she thinking an abortion had been performed. Vomiting ceased and on return of same was soon relieved by same method. No vomiting after sixth month. Patient was delivered at term.	Med. Annals, Albany, 1882, iii. p. 226-228.
7	T. C. Wallace, M.D., Cambridge, N.Y.	?	P	8th week.	13th wk.	Everything internally. Copeman's method. Nitrate of silver (solid) to cervix. Relieved by pop-corn.	Recov.	"Confined to bed for more than four weeks, pale, languid, pulse 120 and weak, and so prostrated as to be unable to raise head from pillow. For the past sixteen days her stomach has absolutely refused to retain anything; everything, food, medicine, even a swallow of water being instantly rejected." Rectal alimentation only for past six days. Immediate relief after pop-corn.	Med. and Sur. Rep., Phila., 1883, xlviii. p. 172.
8	John N. Upshur, M.D.	24	P	7th week.	10th wk.	Internal treatment failed. Relieved by Hodge's double lever pessary (closed).	Recov.	Retroversion discovered on 10th week. Relieved by pessary. Previous to insertion of pessary, patient's condition became steadily worse, she "becoming more prostrated and her disgust of food increasing daily."	Am. J. Obst., N. Y., 1884, xvii. p. 915, 917.
9	J. W. Ayle, M.D.	?	M	2d month.	2d month, 2d week.	Relieved by Horsford's Acid Phosphate and chicken-water, other internal remedies having failed.	Recov.	"Nausea and vomiting ceased." "Acted like a charm."	Med. Sur. Rep., Phila., 1884, p. 757.
10	Dr. Prewitt.	Young.	?	About 2d month.	?	Morphine subcutaneously.	Recov.	"Not a particle of food for a week" previous to morphine treatment. Patient was kept under the influence of morphine all the time. "Takes none now, though she did get somewhat of the habit."	St. Bartholomew's Hosp. Rep., Lond., 1883, p. 257.
11	C. E. Stedman, M.D., Boston, Mass.	Young.	M_1	4th week.	14th wk.	Everything internally. Etherial tinct. of iodine to cervix. Rectal alimentation.	Recov.	First labor normal. "When I visited her remedies prescribed had lost effect, and she was in an alarming condition; every particle of food had been rejected for forty-eight hours. Patient had headache, fleeting delirium, pinched countenance, dry brown tongue, constant nausea, little sleep, epigastric and abdominal pain, vomiting up everything, and rapid pulse. The os was patulous and very red. Cervix was flexed and very soft. External Tr. Iodi applied to cervix liberally. Vomiting ceased in twenty-four hours. Patient vomited only twice after that time."	Boston Med. and Sur. J., 1883, 109, p. 529.

TWENTY-EIGHT CASES OF UNCONTROLLABLE VOMITING, IN WHICH ARTIFICIAL ABORTION WAS NOT INDUCED. (*Continued.*)

No.	Reported by.	Age.	Multip. or Primip.	Vomiting, Began.	Vomiting, Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
12	Henry F. Campbell, M.D., Augusta, Ga.	29	M_2	?	About 16th wk.	Everything internally. Nitrate of silver (solid) to cervix. Rectal alimentation alone for 52 days	Recov.	Patient aborted at three and one-half months. Fœtus dead. Nausea did not cease for over two weeks, during which time she was nourished solely by enemata and for a much longer time this "had to be continued as supplementary to her very gradually returning power to take and retain food by gastric ingestion."	Gynæcological Transactions, 1878, iii, 268-298.
13	Henry K. Leake, M.D.	?	?	9th week.	12th wk.	Everything internally. Cervix thoroughly dilated.	Recov.	Labor set in (probably due to dilatation of cervix) about the 12th week. "Patient recovered after a slow and painful convalescence from a pelvic cellulitis, which supervened on the expulsion of the fœtus. Immediate relief to vomiting after abortion."	Med. Rec., N.Y., 1885, xxvii, p. 256.
14	W. J. Collins, M.D.	38	M_7	$4\frac{1}{2}$ mos.	$6\frac{1}{2}$ mos.	Internal remedies only.	Recov.	Patient aborted at six and one-half months. Labors natural before.	St. Bartholomew's Hosp. Rep., Lond., 1883, p. 125.
15	Dr. Murphy, London.	?	P	Almost from time of conception.	About 3d month.	Internal remedies only.	Death.	"About the third month it (the vomiting) became so severe as to cause great emaciation and exhaustion." Several remedies were used to no purpose, and at the eleventh hour the question was asked:—"What further could be done?" She was fast sinking; the time was past to attempt the induction of permature labor, and she died in about two days afterwards."	Murphy's Midwifery, 2d ed., p. 94.
16	Dr. Haighton.	?	M_4	About 6th month began to grow worse.	Probably about $7\frac{1}{2}$ months.	Internal remedies only.	Death.	"She had most obstinate vomiting in two previous pregnancies." Sickness would sometimes intermit. Slight improvement caused the doctor to defer artificial abortion. The next day she was taken exceedingly ill and died in two days.	Obst. Med., vol. ii, p. 871.
17	Dr. Johnson.	30	P	?	4th mo.	Internal remedies only.	Death.	"Pregnancy was not detected, but the disease was attributed to the pylorus." "The sickness (vomiting) and emaciation were the only symptoms present." "She died, and after death no morbid appearances were observable in any part of the body. The uterus contained a fœtus about four months old. This patient was literally starved to death."	Lancet, Lond., Mar. 3, 1838, p. 825.
18	J. Marion Sims, M.D., N. Y.	Young.	P	2d week.	?	Internal remedies only.	Death.	Artificial abortion advised and refused. Died of heart clot started up "by getting out of bed to answer a call of nature."	Arch. Medical N. Y., 1880, iii. 269-276.
19	Geo. Davenport, M.D., E. Randolph, Vt.	25	P	?	?	Internally only.	Death.	Married about one year. Attacked with nausea and vomiting and died in five weeks in spite of all treatment. Pregnancy was not recognized, the diagnosis being a low form of bilious vomiting, great emaciation. Pregnancy confirmed by autopsy.	Tr. Ver. M. Soc. 1878, St. Albans, 1879, p. 39, 40.
20	Geo. Davenport, M.D., E. Randolph, Vt.	Young.	P?	5th week.	12th wk.	?	Death.	"She died of exhaustion."	(Same as above)
21	Geo. Davenport, M.D., E. Randolph, Vt.	Married several years. ?	?	?	?	Internal remedies. Morphine per rectum.	Death.	"Called in consultation." "She gradually sank and died."	(Same as above)
22	W. S. Brown, M.D., Stoneham.	26	M_2	About the 12th wk.	16th wk.	Internally only. Usual remedies had no effect.	Death.	"Labor pains set in on October 14th, about 2 A.M., and the fœtus was expelled at 7 A.M." "Convulsions and coma supervened and terminated the scene about 9 A.M." "One thing remarkable was the absence of emaciation." The question occurs, "What was the cause of death?" "It was not due to starvation, nor to Bright's disease, nor to any operation upon the womb. Exhaustion of nervous energy, therefore, seems the most probable answer."	Jour. of the Gynæcological Soc. of Boston, vol. ii. p. 208.
23	A. H. P. Leuf, M.D.	22	P?	Probably 6th to 8th week.	About 12th wk.	Internally only. Pregnancy not suspected.	Death.	The patient was not married. Pregnancy was not suspected. "The case was mistaken for gastric ulcer." "The symptoms also pointed to a local gastric	Proc. Med. Soc. County Kings Brook'n 1883, 1834, viii. 48-50.

TWENTY CASES OF UNCONTROLLABLE VOMITING OF PREGNANCY, IN WHICH ARTIFICIAL ABORTION WAS INDUCED.

No.	Reported by.	Age.	Multip. or Primip.	Vomiting. Began.	Vomiting. Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
1	Dr. Churchill.	Young.	M_2	About 4th month.	6th mo.	Internal treatment failed. Ovum punctured, followed by ergot.	Recov.	"We tried all the usual remedies with occasional relief, but the vomiting returned, and finding that she could retain no nourishment whatever, that her bodily powers were worn out, that her pulse was steadily 120, I determined at the sixth month to induce premature labor." "She was delivered of a dead foetus, recovered rapidly and has since born a child at full time."	Churchill's practice of midwifery, 4th edition.
2	J. Farrant Frye, Swansea.	37	M_2	Probably about 4th month.	?	Internal remedies failed. Artificial abortion. Method not stated.	Recov.	"The patient's condition became desperate; labor was induced as the only means of saving life."	British M. J., 1880-1, p., 399.

No.	Reported by.	Age.	Multip. or Primip.	Vomiting. Began.	Vomiting. Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
3	W. J. Collins, M.D.	26	M_4	About 6th month.	?	Introduction of a gum elastic catheter 8 inches.	Recov.	"Vomiting ceased immediately after birth."	St. Bartholomew's Hosp. Rep., Lond., 1883, p. 123.
4	S. G. Moses, M.D., St. Louis, Mo.	Under 30 years.	M	?	Between 2d and 3d month.	Bougie to fundus between membranes.	Recov.	"Never vomited after introduction of bougie and eventually aborted."	St. Louis Courier of Med., 1884, 11, p. 252.
5	S. G. Moses, M.D.	Under 30 years.	M_2	?	Between 2d and 3d month.	Ovum punctured.	Recov.	"When first seen was in moribund condition." Out of danger in twenty-four hours. In first pregnancy vomited several weeks and then aborted, with relief from vomiting. Several children since without trouble.	St. Louis Courier of Med., 1884, 11, 250-262.
6	R. Scot-Skining, M.B. et Ch. m., Edin., Phys. to the Prince Alfred Hospital, Sydney.	21	?	3½ mo.	About 7th mo.	All the usual medicinal remedies were exhausted. Finally, introduction of bougie and dilatation of cervix with Barnes' fluid dilators.	Recov.	Patient was a passenger on board an emigrant ship, sailing from Plymouth, Eng., to Australia. "The morning sickness was intensified by sea-sickness." Bass' Ale was retained when all else was immediately vomited. "For the first few days after delivery the patient remained in a very low state, but with the entire absence of the distressing vomiting which had before existed. Food was now readily retained, and in an astonishing short time I had the satisfaction of seeing her in a condition which removed all further anxiety from my mind."	The Australasian Medical Gazette, Sept. 1884, vol. iii. No. 12.
7	Dr. Scott.	? Probably young.	P	6th week.	10th wk.	Artificial abortion. Method not stated.	Recov.	"Nausea left from time fœtus came away."	St. Louis Courier of Med., 1884, 12, p. 61-67.
8	Dr. Coles.	?	?	?	?	Artificial abortion. Method not stated.	Recov.	Patient was relieved from nausea and vomiting instantly.	St. Louis Cour. of Med., 1884, 11, p. 259-260.
9	Dr. Ward.	38	P	?	"In the 8th mo."	Everything internally failed. Induced abortion. Hot douche to internal os followed by Barnes' dilator.	Recov.	Patient was seen "on account of such excessive prostration due to continuous vomiting." "Every therapeutic means had been adopted without avail." Podalic version. Dead hydrocephalic child with peeling epidermis. "In less than twenty-four hours she was able to retain whatever nourishment was given." Rapid recovery.	N. Y. Med. J., 1880, xxxi. p. 406.
10	Wm. Warren Potter, M.D., Batavia, N.Y.	23	P	? Probably about 10th week.	14th wk.	Internal remedies failed. Nitrate of silver. Tinct. iodi. locally failed. Artificial abortion.	Recov.	"There was inter-current catarrhal bronchitis present." "Rectal alimentation and medication having failed to arrest the progress of malady, the direful alternative of putting an end to the pregnancy was forced upon me."	Am. J. Obst., 1880, xiii., p. 85, 98.
11	M. H. Jordan, M.D.	24	P	?	14th wk.	Internal treatment failed. Nitrate of silver to cervix failed. Artificial abortion. Cervix dilated and fœtus scooped out by hand.	Recov.	"When first seen, patient had been confined to bed for five weeks with a distressing and uncontrollable nausea and vomiting." She was much emaciated, quick pulse, some fever, and retained comparatively nothing on her stomach." There was considerable difficulty in bringing on labor pains but finally it was successfully accomplished. Patient was so weak at time of abortion, that she could not turn herself in bed. "After the operation she never became sick at the stomach, or vomited a single time." In two weeks she was able to be carried home from Birmingham, Ala., to Chattanooga, Tenn. "If this woman had not have aborted, she certainly would have died."	Ameri'n Pract., Louisville, 1879, xx. 305-309.
12	W. T. Wright, M.D., Winfield, Kansas.	24	P	6th or 7th week.	About 10th wk. Thirteen days after serious symptoms set in.	Everything internally with failure. Artificial abortion. Pains set up by electricity, ergot sounds and tents failing.	Recov.	"Pulse gradually rose until it reached 140-150 at time of abortion, at which time the following conditions were present:" "She was a fleshy woman, now the skin hangs loose on her limbs, eyes deeply sunken; a markedly pinched appearance of her features. Respirations 40 per minute, pulse rapid and indistinct, surface hot and dry, extreme dyspnœa, restless throwing about of limbs, general tremor. On the day following the abortion she called for food which was relished and retained.	Peoria Medical Month., 1883, 4, iv., p. 6-14.

TWENTY CASES OF UNCONTROLLABLE VOMITING, IN WHICH ARTIFICIAL ABORTION WAS INDUCED. (*Continued.*)

No.	Reported by.	Age.	Multip. or Primip.	Vomiting. Began.	Vomiting. Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
13	T. G. Thomas, M.D., New York.	? Young.	P	3d week.	10th wk.	Artificial abortion. Cervix dilated and fœtus and placenta scooped out with ordinary wire curette.	Recov.	Patient dispelled a "phantom" tumor about three months before, thinking herself to be pregnant. When first seen had been vomiting two and one-half months. As a result of the vomiting she had become excessively emaciated." After curetting the vomiting ceased at once and patient recovered entirely.	Am. J. Obst., N.Y. 1881, xiv. p. 674.
14	N. C. B. Haviland, M.D., Danville, Vt.	23	?	5th or 6th week.	15th wk.	Internal treatment failed. Artificial abortion by injection of tepid water, one ounce, into uterine cavity.	Recov.	This case was complicated by attacks of petit mal. The hypodermic injection of morphine was the only drug that had any effect. Nitrate of silver to cervix freely, failed, though for a time it seemed beneficial. After labor was started patient fainted at every pain, "rallying by repeated hypodermic injections of brandy and liq. ergotæ." After delivery, "no symptoms of fainting again occurred, and patient immediately commenced to take cracked ice and brandy, with no return of nausea." Patient had a tedious recovery and has since had irregular attacks of petit mal.	Am. J. Obst., 1883, xvi. No. 2, p. 165-168.
15	Geo. Davenport, M.D., E. Randolph, Vt.	34	M_5	4th wk. ?	6th or 7th week.	Internal remedies failed. Artificial abortion — sound introduced.	Recov.	No nourishment in stomach for over two weeks. Life sustained solely by nutritive enemata. Pulse 120-130. "Could not turn herself in bed," nor move her lower limbs. Features pale and sunken. Death appeared inevitable. "The patient, notwithstanding her great prostration, made a good recovery, slowly to be sure, but with not one untoward symptom."	Tr. Ver. M. Soc. 1878, St. Albans, 1879, 39, 49.
16	See reference.	20	P	5th wk.	About 17th wk.	Internal remedies failed. Tr. iodi. to cervix. Artificial abortion by means of sponge-tent and sound passed into uterine cavity.	Recov.	Patient was unmarried. Last catamenia Dec. 25, 1868. Nausea two weeks later. Vomiting began on 5th week. Entered Boston City Hospital, February 6, 1869. On February 25, vomiting having continued almost incessantly, the following condition was present: — "Has lost much flesh, cheeks flushed, countenance haggard, conjunctivæ suffused, eyes dull, tongue red without coat, pulse 132 and very small — os uteri to be dilated by sponge tents." February 28 — "Large sponge tent withdrawn, leaving os fully dilated." "Sound passed in about three inches, very little hæmorrhage followed — no severe pain." March 1 — Vaginal examination shows external os dilated, but internal os closed. Patient's condition remained about the same until March 31, when she was seized about 9 P. M. with sharp pains in hypogastric region, which by morning assumed a bearing-down character. Pains lasted about twenty-four hours, when both fœtus and placenta were expelled, scarcely any hæmorrhage following. Patient made a slow, tedious convalescence. Vomiting did not entirely stop for over three weeks. Was discharged well, June 10, patient being in hospital four months and four days.	Boston City Hosp. Med. Records, vol. 35, p. 132.
17	Geo. T. Elliot, M.D., New York.	32	M_9	About 6th month.	Between 7th and 8th mo.	Internally everything failed. Artificial abortion by means of hot douches.	Death.	No trouble with previous labors. "Supporting treatment was resorted to by the mouth and rectum, but she steadily lost ground from the date of her admission (to hospital.)" Child born living apparently between seventh and eighth months, small and puny. "Patient died in about ten hours." "Intelligence uninterruptedly clear, vomiting never having been checked."	Obst. Clin., p. 167.

No.	Reported by.	Age.	Multip. or Primip.	Vomiting. Began.	Vomiting. Ended.	Treatment.	Termination.	Condition and Remarks.	Reference.
18	Dr. Engelmann, St. Louis, Mo.	Young.	P	?	6th mo.	Artificial abortion.	Death.	"Patient died in eight to twelve hours after abortion was produced. Vomiting was finally stopped by application of carbolic acid to cervix and a tampon of tannic acid, glycerine and carbolic acid; and it was thought possibly the chances might be better if the ovum were removed."	St. Louis Courier of Medicine, 1884, 12, p. 61-67.
19	S. G. Moses, M.D., St. Louis, Mo.	Under 30 years.	P	?	Between 2d and 3d month.	Artificial abortion. Ovum punctured.	Death.	Patient had been "vomiting for five or six weeks almost incessantly; could retain absolutely nothing." At time of abortion patient was moribund, feeble pulse, fetid breath and foul tongue. Vomiting ceased in twenty-five or thirty minutes. "Death from absolute starvation."	St. Louis Courier of Med., 1884, 11, p. 250-262.
20	S. G. Moses, M.D., St. Louis, Mo.	Under 30 years.	M_2	?	Between 2d and 3d month.	Artificial abortion. Ovum punctured.	Death.	"Persistent vomiting." "Could retain nothing." After abortion, vomiting stopped. Patient "actually starved to death." Died in twelve hours.	St. Louis Courier of Med., 1884, 11, p. 250-262.

SUMMARY.

Recoveries.....16 (Multip. 6; Primip. 7; Not stated 3)

Vomiting relieved by abortion instantly or very soon 2
Vomiting relieved before abortion..... 1
Vomiting not relieved by abortion..... 1
} with death.

Deaths.....4 (Multip. 2; Primip. 2)

Average time of death after abortion, in 3 cases.....10⅔ hours.
Average time of death after abortion, in 1 case.....Not stated.

Vomiting relieved by abortion instantly or very soon (a few hours).....11
Not stated in report.....4
Not relieved (for three weeks).....1
} with recovery

I have thought it might be interesting to compare the results of treatment in all the well marked cases of this affection that I have been able to find reported, and hope that it may lead to a full conference of opinion by the gentlemen present, as to their individual ideas regarding this disease and their experience in the treatment of the same.

RECURRENT HEADACHE IN CHILDREN, AND ITS TREATMENT.

BY RUSSELL STURGIS, M.D.

IT is not uncommon to see children complaining of headache whose general health is apparently good. Such children usually are troubled with headache more or less severe, recurring at intervals of days or weeks, and each attack lasting from a few hours to a day or more. You will generally find that the child has been subject to these headaches for a year or more before treatment is sought for this particular symptom. As a rule, it will be noticed that the patients are of nervous temperament, that they do not sleep well, that they grind their teeth at night, and frequently suffer from bad dreams and nocturnal terrors. Frequently these children will have a spasmodic cough, particularly at night, even if there be no signs of pharyngitis or laryngeal irritation to account sufficiently for such cough. It may be noticed that the child has difficulty in keeping its hands quiet, that if told to keep standing quietly it will constantly change its weight from one foot to the other. In temper the child is apt to be fretful. Nothing particular is to be noticed about the face with the exception of a peculiar heavy expression about the eyes. This expression is noticed in people with migraine, and also in any depressing illness. Dr. Warner,[1] after careful examination, thinks this expression is due to lack of tone in the orbicularis palpebrarum, giving "an appearance of flabbiness about the lower eyelid; the skin hangs too loose with an increase in the number of folds, and in place of falling neatly against the lower eyelid as a convex surface, it falls more or less in a plane from the ciliary margin to the lower margin of the orbit, a condition often best seen in profile." This heavy expression about the eyes is not noticed in all cases of recurrent headaches.

These headaches generally come on in the morning, though the child may be perfectly well on going to bed the night before. The pain is generally localized in some particular part of the head, either side, frontal region or vertex. The pain is severe, during the seizure, usually preventing study or play. It is not unusual for there to be optical illusions of sparks, or bands and spots of color. There may or may not be nausea during the attack. The child generally feels cold, and in winter prefers to lie near the stove huddled up in a chair.

The picture is very like that of migraine in the adult, with this difference: the pain is more apt to be across the forehead and may be at the base or at the vertex of the skull; there is rarely vomiting or nausea with the attack, and such attacks seem to yield to a treatment which is of very little use in hemicrania of the adult.

Dr. Eustace Smith in his latest book, considers the headaches identical with migraine. Dr. Warner is inclined to think that these recurrent attacks are but a mild form of chorea. It has been shown by Dr. Hughlings Jackson and by Dr. Herman that in cases of chorea about seventy-five per cent. of the children suffered from recurrent headaches.

Since 1882 I have seen sixteen cases of recurrent headache. At first I spent a long time unsuccessfully in trying to relieve the patient by attention to diet and

[1] Physical expression.

hygienic surroundings, by general tonic treatment and the exhibition of citrate of caffein and guarana. At last, remembering what Niemeyer calls the "fanciful hypothesis of Du Bois-Reymaud and Möllendorf," that the pain may be due to excitement of the terminal sensory filaments of the fifth pair by dilatation of capillary blood vessels of the dura mater, I thought I would use ergot for its effect on the circulation through the arterioles. The results have been highly satisfactory. The longest time required to free a patient from the attacks has been four weeks. In one case two doses of ergot gave relief.

It has been my practice to give m x of the fluid extract three times daily after meals, and to continue the treatment for two weeks at least after disappearance of pain. I generally have used ergot alone, but in one case combined it with iron. Dr. Eustace Smith[2] uses strychnine in combination with ergot. I give below four typical cases. Case I and III were brother and sister; they were both rather tall children for their ages, had the heavy expression of the eye extremely well defined. Their mother, when a child, suffered from recurrent headaches but had "outgrown" them. The pain in these two cases was across the forehead. Nervous symptoms were not well marked in these two cases. Case II had pain in the right side and was decidedly a nervous child. Case IV had his attacks at night with pain at the vertex, and did not respond quickly to treatment. In no cases could abuse of tea be held responsible for these headaches.

Case I. L. B., age thirteen, first seen November, 1882. She is a tall, well nourished girl, rather anæmic in appearance. Lives in a nice sunny house in a good neighborhood. She began to complain of headaches about three years ago, but they did not recur with sufficient frequency to make it worth her mother's while to have them especially treated. Now she has a headache as often as three times a week, lasting generally from when she gets up in the morning till when she goes to bed at night. During the attack of headache she never has nausea but frequently sees sparks of light or spots of red. Nothing but slight astygmatism was detected on examination of the eyes. Suitable glasses were provided without diminishing the frequency of recurrence of headaches nor their severity. I kept her for some time under general treatment, using tonics, sedatives, etc., and also using specific remedies for headache, such as guarana and caffein till January, 1883, when I began the use of ergot, m x fluid extract. Improvement was marked in a few days, and she remained free from headaches till the following October, when a course of ergot again relieved them and she has continued free from them since.

Case II. J. S., age eight years, March, 1884. A small black-haired fidgety Irish girl, not anæmic, well along in her studies, and very ambitious, fond of school and of playing out of doors. I had seen this same child before when suffering from headache, due, I thought, to the abuse of tea. On my advice she gave it up and had not taken any for about three months, when I saw her in March. She complains solely of headache coming on about once a week and lasting not more than twelve hours at a time. There were no signs of chorea in her case, with the exception of her unwillingness to stand still for more than half a minute at a time, when I was talking to her, and a moving about of her hands, which, however, was under control of the will. Nothing abnormal in eyes. After two weeks treatment she was relieved of her headaches, and the mother told me about a month ago that she had had no return.

Case III. F. B., age eight years, June, 1885. A brother of Case I, complains of the same headaches that his sister used to have, the pain in the frontal region as with her. Has very much her appearance, the heavy expression of the eyes being particularly well marked. Appetite is fair. The attacks in this boy come on about once a month, and last one or two days at a time. He has nausea towards the end of his attack of headache. Urine normal. The present attack disappeared after three doses of ergot, which, however, was exhibited for two weeks longer. He has not suffered from headaches since.

Case IV. I. M., age eleven years, November, 1885. An Irish boy fond of play but not of school. General health all that can be desired. He is free from headache during the day, but at night is waked up by pain across the vertex. He thinks the attacks last about one hour and then pass off, to recur again perhaps before morning; he has generally two bad nights each week. This case was examined with great care but nothing abnormal detected in the eyes, nothing wrong about the urine, and no reason to make a diagnosis of cerebral disease. His headaches gradually disappeared after continued use of ergot for four weeks. He is now free from his pain.

[2] Disease in Children, 1884.

RECENT PROGRESS IN LEGAL MEDICINE.

BY F. W. DRAPER, M.D.

ON THE IDENTIFICATION OF HUMAN BLOOD.

To the solution of this important and still unsettled medico-legal question, Dr. Masson, "Pharmacien-major" of the French army, has contributed an elaborate series of original observations.[1] After an interesting historical review of the subject, showing the gradual and progressive transition from the crude chemical tests of Orfila's time to the period, beginning with 1857, when Robin relegated chemistry to a place of secondary importance in the diagnosis of suspected stains, and asserted that the microscope was the true master of the situation, the author quotes from many distinguished writers and experts — Virchow, Roussin, Blondlot, Rabuteau, Malassez, Hofmann, and others — to show how varied, and sometimes contradictory, are the opinions of men of the highest authority concerning blood-stains. Each observer has looked at the problem from the point of view of the case of homicide which was presented to him, supporting his conclusions upon parallel experiments, under conditions identical, as nearly as possible, with those of the affair in hand, rather than upon principles acquired scientifically. The composition of the fluids used to restore the dried blood-globules has varied with each observer; some were acid, some alkaline, some of seemingly neutral effect upon the globules, some distending, and others contracting them. Under such circumstances, it is not strange that great diversity of conclusions should result. Some declare that a certain kind of fluid has power to restore to the globules their normal characters of form and size; others recognize the

[1] Annales d'Hygiène Publique et de Médecine Légale, May and June, 1885.

power of the solution to isolate the globules, and no more; some state their ability to restore the corpuscles in great numbers; others can find only two or three satisfactory elements in any one preparation, and these with difficulty; for some, the globules, under their manipulation, become just like a preparation of fresh blood; with others, they remain irregular, distorted, unrecognizable; certain experts declare that it is an easy thing to identify human blood-globules, and to affirm their presence in a stain; with the great majority, it is impossible. How this uncertainty weighs upon the expert, who, called upon to pronounce on a subject so grave, seeks vainly for a guide which shall teach him within what limits he can, and ought to enlighten justice!

In the presence of these rather discouraging conditions, Dr. Masson undertook a series of independent inquiries, designed to elucidate the following points:

(1) To determine, under the various circumstances in which the question may be presented to the expert, the artificial fluid which gives, with human blood, the preparations most favorable for micrometric purposes.

(2) To study the causes of the changes in blood-globules, and to define their effects as far as possible.

(3) To experiment upon the blood of animals simultaneously with that of man, and to ascertain within what limits the expert may be positive as to the origin of the blood in a given case.

In experimenting with fresh blood, whether clotted or liquid, Masson found Vibert's fluid the most useful for preserving the globules in their normal form and volume; this fluid is composed of bichloride of mercury (five parts), chloride of sodium (twenty parts), and water (one thousand parts).

If the blood has become dried upon surfaces and substances which are not porous, Virchow's fluid (liquor potassæ and water) gives the best preparations for the microscopic examination of blood-stains. This solution sets free the globules by dissolving the substance which holds them; it leaves a clear view of the corpuscles unobscured by debris. It is not necessary that the stain should be either large or thick; a little spot of blood, no larger than the head of a pin, if it be found on an impervious surface (the blade of a weapon, a pavement, a wooden floor, bone or metallic button, wainscoting of a room), will give better results, under the action of the potassa solution, than a linen or cotton shirt fully covered with blood-stains.

In discussing this latter condition, the presence of blood-stains on various fabrics, the author distinguishes two kinds of material: according as it is, or is not, moistened by the blood through capillary action of the fibres. If a drop of blood falls upon felt, it tends to preserve its spherical shape and to dry upon the surface of the wool, without penetrating it. If, on the contrary, the fabric is of a nature to absorb the blood, and to become moistened by it, the capillary phenomena result in the dispersion of the blood-globules, which are found encasing each filament of the cloth, while the plasma penetrates the filament itself.

When the crust of dried blood is found upon the fabric, without having penetrated it, the same manipulation which is useful in blood-stains upon impervious surfaces (wood, metal) is available, and Virchow's fluid is the best. But in dealing with porous fabrics, the author's results were uniformly unsatisfactory. Whether the stain be days or months old, whether one uses the powder obtained by unravelling the dry tissue holding the stain, or first moistens it by imbibition or maceration, the fluid used is powerless to restore the distorted and shrunken globules. The cotton, linen, or hemp fibres appear covered with a yellowish gloss, forming a sheath which may be removed by careful manipulation. This sheath is found to be made up of irregular, shrivelled, and closely-welded globules, forming a true mosaic upon the filament. Isolated globules may sometimes be seen lying outside this compact sheath, but these are always shrunken and out of shape. Very rarely, a single globule is found which has escaped the common lot and has kept its form, and, perhaps, its normal volume. The separation of the welded mass of globules is not an easy matter; unless the expert uses great care, he runs the risk of mistaking for isolated corpuscles, fragments made up of the remains of adjacent corpuscles. The search for globules of normal form and size, in blood-stains on linen or cotton cloth, will be fruitless; the expert may be able to declare that the stain is a blood-stain, and to distinguish the globules of mammals from those of birds by the nuclei in the latter, but that is all. The only exceptions to this are cases, in which the blood is in sufficient amount to form crusts, or in which it has dried on the surface of fabrics of very close texture.

As causes producing modifications in the shape and size of blood-globules, as they are found in stains, the author names the nature of the surface on which the stain is found, the thickness and age of the stain, its desiccation, and the temperature and moisture of the surrounding air. Age does not appear to have a very important influence; whether the stain be one day, or ten months old, its elements are not appreciably different. Once dried, the globule does not tend to change farther. But it is an error to assign a destructive action to desiccation. When the drying process is rapid, it fixes the globules at once in their primitive shape, without modification of their dimensions. Acting on this principle, Welcker has made measurements whose value has been recognized as perfectly exact by all hematologists; he places a minute drop of blood upon a glass slide, heated to 60° (C.), and spreads it immediately in a thin layer, by means of a needle held horizontally.

But if the desiccation is slow, the globules remain very fragile, and very ready to take on changes in form and size. Thus, moisture in the air, as it retards evaporation, is one of the more important agents in causing the changes described. To study this influence, and to define its effects as far as possible, the author placed drops of blood on different surfaces (glass, a knife-blade, wood, pebbles, cloth), and these he put under a bell-glass over a saucer filled with water. After a fixed period, the blood was examined upon its removal from the moist chamber, before drying, and after. The globules showed essentially the same appearances under the microscope, at the moment of removal from the bell-glass, and after their desiccation.

In dried blood, the blood-globule resists, for a very long time, all conditions which otherwise would change it. No fluid known can restore to the altered blood-globule its primitive form and dimensions. Once distorted and shrunken, all the blood-globules of mammals are alike. The contraction of the globules being accompanied by characteristic changes in shape, very easy to distinguish from those which result from reciprocal compression, whenever a globule has preserved

its flattened, bi-concave clearly-outlined shape, it must be regarded as normal, and as a standard for measurement. But when the globule is altered in shape, the expert should acknowledge his inability to make a diagnosis of its origin.

The closing section of Dr. Masson's article is devoted to a study of the micrometry of blood-globules. He quotes Vibert's remark, that the diameter of blood-globules varies within limits which are relatively considerable, not only in the same species, but in the same individual; that the most competent observers are far from giving the same average diameter, or the same maximum or minimum diameters to the globules of the same animal; that, assuming the corpuscles to have absolutely fixed dimensions, it is not possible to distinguish with certainty, one with a diameter of 0.0075 mm. (man), from another with a diameter of 0.0073 mm. (dog). Masson emphasizes the necessity of making many observations, of taking the mean of fifty or a hundred diameters in any given case, instead of relying on the dimensions of any single globule.

The greatest cause of error results from the variable diameters of globules from the same individual, an error very difficult to control. Another source of error lies in the fact that pathological changes may occur in the globules to modify their size. The measurement of globules from fresh blood is a rare necessity in legal medicine; the expert has to deal with old and dried stains. To the examination of these latter, the author has devoted most of his attention. We have space for a few of his results only. The blood-globules of birds and fishes, when dried on cotton or linen cloth, lose their elliptical shape, and become shrunken and irregular; their nucleus is the one essential and permanent characteristic which distinguishes them from mammal globules. Human blood-globules resist change better than those of other mammals; they also have a deeper color. But much depends upon the substance and surface where the blood-stain is found; stains on cotton, or other absorbent fabrics, if derived from mammals, cannot declare their origin to the microscope, their globules having became greatly altered, as described previously.

Where, however, the material for microscopic study is a bit of dried crust of blood, found on an impervious surface, it may be possible, after taking the average of many measurements, to distinguish the origin of the blood in the stain submitted to the expert. In many cases, however, the conclusion amounts to a probability only, unless we are dealing with the blood of fishes or birds, which is distinguished from human blood with comparative ease. The author found that, as the result of his great number of examinations, made under favorable conditions, it was easy to differentiate human blood-globules and those of the pig, the ox, and the cat; a delicate matter to settle the difference between the blood of man and that of the dog; still more uncertain when rabbit's blood was in question, and impossible to decide between human blood and that of the guinea-pig.

CHRONIC ALCOHOLISM.

Alcohol plays such an important part in most medico-legal affairs, that new light upon the anatomical changes wrought by this agent must always be welcome to the medical jurist. Dr. Formad recently presented to the pathological Society of Philadelphia,[2] an analysis of two hundred and fifty autopsies on the bodies of drunkards, illustrating the most prominent anatomical lesions of chronic alcoholism. He considered the most conspicuous changes to be cyanotic induration of the kidneys, fatty infiltration of the liver, and mammillated stomach. His cases had been those in which there was a history of a long-continued series of debauches, of subjects dying in one of these debauches, and did not include moderate drinkers, or those who perished after an enormous quantity of alcohol, without any previous chronic excesses. He thought that the exposure, irregularities of diet, etc., incident to a state of drunkenness, had much — probably more than the alcohol itself — to do with the production of the lesions, but it is not at all possible to separate one from the other. He gave a long list of morbid changes, considered by various authors to be the results of chronic alcoholism, among which cirrhotic liver, with contraction, holds a prominent place. He had himself, at one time, considered cirrhosis a very frequent, if not an almost necessary concomitant of long-continued excessive use of alcohol, and had testified in court, that a certain person was not likely to have been a hard drinker, because, at the autopsy, no cirrhosis was found. He had thought, too, that the connection between the two is so close, that it is impossible to have a case of cirrhosis without a history of alcoholism, as is held by various authors. Therefore, it was surprising to him to meet in the two hundred and fifty autopsies, with only six cases of cirrhotic contraction of the liver. In two hundred and twenty cases, the liver was considerably, or even very much enlarged, the enlargement, in most cases, being due to fatty infiltration. Cyanotic induration of the kidneys and chronic gastritis, with mammillation of the stomach, were found in nearly every case. This cyanotic induration is peculiar and differs from that due to heart disease.

In the course of the discussion, Dr. William Osler said that his own experience with livers in a large number of autopsies in cases of chronic alcoholism, had led him to divide them into four classes: (1) Those in which the condition is pretty satisfactory; some individuals may take alcohol for many years, and yet the liver will pass muster. (2) Fatty cirrhotic livers; the cirrhosis may not be distinct to the naked eye, but is plainly shown by the microscope. This is the largest class. (3) "Hob-nail" livers; these, he would say, were much more common than in Dr. Formad's series. (4) Hypertrophic cirrhotic livers. In order of frequency, he would place the pathological changes in the liver, due to alcohol, as follows: fatty cirrhotic, hob-nail, hypertrophic cirrhotic, apparently normal.

RARE GUN-SHOT WOUNDS IN SUICIDES.

Professor Maschka, of Prague, medico-legal counsel for the Bohemian government, calls attention to the fact that, while suicides, in shooting themselves usually choose a part of the body which is easily accessible to them, cases of self-destruction by shooting do occur where the wound of entrance is found in extraordinary places, parts which, of course, must be within reach of the muzzle of the weapon in the hands of the suicide, but which are so unusual as to give rise to grave suspicion of homicide.[3] Especially does this suspicion arise where no details of the death are known or the body is found in an isolated spot, open to others.

[2] Medical News, November 21, 1885.

[3] The Medico-Legal Journal, September, 1885, page 227.

Maschka relates two illustrative cases, both of undoubted suicide. In one case, the bullet entered the head "somewhat to the left and about two and a half centimetres back from the top of the head." The hair around it was singed. The whole occipital region under the scalp was covered with extravasated blood. The bullet was found at the base of the brain between the left middle and posterior lobes.

In the other case, a young man was found in his room, lying dead upon a sofa, with a revolver by his side; the officers found the door of the room fastened on the inside. Post-mortem examination showed on the top of the head a small round wound with blackened edges, beneath which was found a bullet completely flattened and lying close to the bone. There was a depressed fracture of the skull at a point fifteen millimetres above the apex of the lambdoid suture and to the left of the sagittal suture. There was a second wound below the left nipple; this, on dissection, was found to involve the left lung, the pericardium, and the heart. It appeared that the suicide, failing to accomplish his purpose with the shot in the back of the head, directed a second and more successful shot toward his heart.

The author concludes that should cases occur wherein the external wound from a pistol is in an extraordinary location and the question of the manner of the death, whether by suicide or homicide, is to be determined, the following considerations are to be remembered:—

1. The possibility of reaching the part of the body in which the wound is located should be decided by the examiner by attempting to place on the corresponding part of his own body the muzzle of the weapon with his right or left hand.

2. Certain well-known appearances, such as burning, singeing, dark discoloration and hardening of the parts close to the wound must be present for a theory of suicide; but they do not prove this, because they do not exclude the possibility of the close application of the weapon by a second person against an individual while asleep, drunk or otherwise stupefied.

3. Other indications, such as signs of resistance, traces of a struggle, of robbery, or of injuries other than the shot-wound should be looked for. The character of the locality, the condition of the clothing and the circumstances under which the killing took place, are to be considered. An apparent motive for suicide should be sought for and any written or verbal expression of an intention to commit the act should be weighed as a basis for an opinion.

[To the second of these propositions, those who have had much experience with gun-shot wounds will be inclined to take exception. The author expresses himself too strongly when he states that "certain appearances *must* be present for a theory of suicide."—REP.]

CHANGES IN THE PUPIL AFTER DEATH.

From an interesting series of original observations upon the eyes of recently dead subjects and upon their behavior under certain physiological stimuli, Mr. J. N. Marshall draws the following conclusions:[4]

"(1) In most cases, the pupils are dilated at the time of death, the dilatation usually occurring within a short period of the fatal event. Dilatation at an appreciable time after death is quite exceptional. This condition is essentially paralytic and is independent of the state of the pupil during life, whether that is altered by drugs or by disease.

"(2) There is, in the great majority of cases, progressive contraction of the pupil after death. This varies within wide limits, both as regards its period of commencement and the degree of myosis attained. It usually begins within an hour after death, and continues for the next forty-eight hours. The contraction which is often unequal in the two eyes, is independent of the action of light upon the eye and of the occurrence of rigor mortis.

"(3) The pupil is susceptible to the action of atropine after death, for a period which probably varies with different subjects, but which may be as long as four hours when simple instillation is employed, and perhaps a little longer when the atropine is injected into the anterior chamber. The dilatation begins at about the same time after instillation of the atropine, as it does after instillation during life, but it differs from the dilatation after the latter in that it is of less degree, and that the influence of the atropine passes off sooner and leaves the pupil to follow its usual course.

"(4) The instillation or injection of eserine after death produces contraction of the pupil, but the period after death during which it can act is shorter than in the case of atropine.

"(5) The instillation of ergotine after death has no effect on the pupil, but its injection into the iris or anterior chamber produces contraction of the pupil up to at least two hours after death.

"(6) Pilocarpine injected into the dead eye has a slight myotic action.

"(7) The removal of the aqueous humor after death does not affect the ordinary behavior of the pupil.

"(8) Flaccidity of the iris during life is exceptional, but it is always present after death, and increases from the time of death onward."

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION OF OBSTETRICS AND GYNÆCOLOGY.

ROBERT B. DIXON, M.D., SECRETARY.

DECEMBER 16, 1885. The meeting was called to order at eight o'clock, DR. JAMES R. CHADWICK in the chair.

DR. O. W. DOE read a paper entitled

THE ADVISABILITY OF INDUCING ABORTION IN CASES OF SO-CALLED UNCONTROLLABLE VOMITING OF PREGNANCY.[1]

DR. FRANCIS MINOT, in opening the discussion, said that much confusion respecting the prognosis and treatment of excessive vomiting in pregnancy might be avoided by dividing the cases into three categories. The first should include those in which the symptoms were moderate, and were easily controlled by suitable diet, by rest in bed for a few days, by regulating the bowels, by the occasional use of small doses of morphia, by the application of sinapisms to the epigastrium, etc. The patients always do well. The second class consists of those cases in which the symptoms are much more urgent, and the patients are in a serious, though

[1] See page 121.

not actually dangerous, condition. They are best treated by rectal alimentation, very little nourishment being given by the mouth, and that chiefly of Ridge's food, Horlick's food, Mellin's food, etc. The best nutritive enemata are composed of peptonized milk with brandy. Morphia is often required at night, and sometimes by day, subcutaneously. Perfect quiet should be enjoined, all talkative visitors being excluded. The position of the uterus should be investigated, and, if necessary, be rectified by suitable intravaginal support. These simple means will generally suffice to restore the patient to health, although they must often be continued for several weeks. It is this class of cases in which what may be called specific remedies have sometimes a remarkable effect, though in the majority of instances they fail altogether, such as the application of strong etherial tincture of iodine, or of the solid nitrate of silver to the cervix, and especially the dilatation of the os uteri, suggested by Dr. Copeman. If one studies the reported cases of cures by these means he will be struck by the absence of details respecting the symptoms, by which one might be able to judge of their severity. Dr. Copeman's method of dilating the os with the finger has now been supplemented by forced dilatation by means of instruments, probably because it was found to fail in so many instances. The truth probably is that these methods are of very little avail, and of none at all unless the general treatment is at the same time carefully carried out. The third class of cases comprises those which are wholly rebellious to any specific treatment, short of induced abortion, and which, in spite of the most careful management by feeding, morphia and seclusion, are very frequently fatal, unless the uterus be artificially emptied before the patient's strength is too far reduced to allow her to rally. An example of this class had lately come under his observation. A young lady was married in June last. She became pregnant early in July. A few weeks afterwards while she was staying at a watering-place, vomiting set in, and soon increased to an alarming degree. She was very judiciously treated by enemata of peptonized milk with brandy, which she retained with ease, and by the subcutaneous injection of morphia. There was but little change in the symptoms, for several weeks, and she was brought to Boston, September 6th, and placed under Dr. Minot's care. She was much emaciated, but though weakened by long continued inanition and incessant vomiting for five weeks, was not exhausted. The treatment was continued, and though at times there was considerable temporary improvement, on the whole the patient gradually lost ground. Although the uterus appeared to be healthy in appearance and position, a soft rubber ring was introduced to raise it as much as possible in the pelvis, though without the slightest beneficial result. The matters vomited consisted of small quantities of bile and mucus, scarcely any food, beyond a little coffee, having been swallowed. As the emaciation and exhaustion were progressing, the blades of a large pair of polypus forceps were introduced into the os uteri, and the cervix was dilated to the extent of nearly an inch. There was no change in the patient's condition in consequence of this operation, which was done September 27th. Accordingly on the 30th, it was repeated, the cervix being exposed with a speculum, and the forceps pushed up to the internal os, but not within it. Dilatation was effected with all the force it seemed prudent to use, causing some pain to the patient and considerable bleeding. As before, the operation was followed by no change for better or worse, in symptoms. It was then decided to take the patient to her home. On the evening of October 3d, she was placed in a sleeping-car, and a full dose of morphia was given just before starting for Baltimore, where she arrived the following forenoon, having borne the journey without great fatigue. Dr. Minot learned that after a few days she rallied a little, and then began to fail again, and it was decided to induce abortion. At the instance of one of the physicians the operation was delayed a day or two in order to allow of a trial of the local application of the nitrate of silver. This expedient also failed completely, and the operation was very skilfully performed by Dr. Howard, of Baltimore, October 26. No blood of any consequence was lost, but the patient sank rapidly, in spite of subcutaneous injections of brandy, and died in about an hour after its completion.

Dr. Minot had had occasion to perform this operation four times for excessive vomiting in pregnancy, the patients having been in each case in a state of alarming prostration. He also introduced a tent into the uterus in a fifth case with the intention of evacuating the uterus, when the symptoms ceased completely, and he declined to proceed farther. The patient, however, was dissatisfied with the result, and afterwards applied to another practitioner who carried out the procedure successfully. In a succeeding pregnancy she came under the care of Dr. Wellington, of Cambridgeport, with a recurrence of the same symptoms, maniacal excitement, with vomiting. Her condition was such that in consultation it was decided to induce abortion, which Dr. Minot did with Dr. Wellington's assistance, and the patient recovered perfectly. The second case was that of a lady who was so much exhausted that it seemed hardly possible she could survive the operation, which however was successfully done, after consultation with the late Dr. Charles Putnam. The vomiting ceased immediately, but many weeks elapsed before she rallied from the state of prostration to which she was reduced. The third and fourth cases were seen in consultation with Dr. Van Slyck, lately of Brookline, Mass. Each patient recovered rapidly after the operation. In conclusion, Dr. Minot said he had but little faith in the specific methods of relieving the excessive vomiting, though the first case above reported shows that occasionally they may be of service. Good nursing, careful feeding, including rectal alimentation, seclusion from all disturbance, and the administration of morphia will suffice, if employed with discretion and perseverence, to relieve a very large proportion of cases. When everything else fails, the induction of abortion is the only hope. If performed with antiseptic precautions, it is generally successful, but, as Dr. Doe well insists, only on condition that it be not too long delayed, and the patient unable to rally after it.

Dr. Fifield said he had seen several bad cases of vomiting in pregnancy, some of which were cured by very insignificant means, such as the application of a handkerchief wet with the tincture of opium and applied over the abdomen. Bromide of potash or choral have produced marked benefit. He mentioned a case of a woman in her second pregnancy said to be two months along. He passed a bougie into the uterus and let it remain over night. In the morning the woman was delivered of a fœtus fully three to four

months old. The woman was relieved somewhat, but the vomiting did not stop, and she sank and died. If the abortion had been induced earlier, the result might have been different.

Another case was that of a woman two months pregnant, and vomiting excessively. Dr. Fifield saw the case, with a Catholic physician. He advised bringing on labor, and the physician resigned the case, his religion prohibiting his being present. Dr. Fifield passed a small bougie but with no result. For three days he tried to empty the uterus, but in vain. The vomiting continued. Finally he succeeded in passing a bent Simpson's uterine sound ten inches into the uterus and vagina. The uterus was ante-flexed. The next morning the ovum had come away. Within six hours the woman retained food, and gradually recovered, sitting up in one week, and she is alive now. It was a charming sight, this sudden change from death to life.

It is not wise to delay long, if relief does not come early from medicine.

DR. DRIVER said that out of twelve hundred cases of pregnancy he has hardly seen a case of uncontrollable vomiting. One case was that of a woman, five months pregnant, who was taken with vomiting and purging in the month of August, and died in three days. It was really a case of cholera morbus. In consultation he has seen two cases of obstinate vomiting. The first was that of a woman six months pregnant, with whom everything had been tried. It was decided to start labor in the evening, but before that time pains came on. The woman vomited some for a year afterwards, and during this time developed paraplegia, recovering after two years. Some time later he was called to see a sister of this woman, and for the same purpose. In her he recognized a former patient whom he had attended at term. At that time, on digital examination, the finger passed into a slit on the right side of the os uteri, which he believed to be the entrance into the right half of a double uterus, and the child was born from the left os. In the present instance examination revealed a double os, symmetrical, with apparently a bag of water beginning to distend each. She was six months pregnant, and the problem was, which side contained a fœtus, or did both, and if a bougie were to be passed up, which side should be selected. Fortunately, pains came on, and it was soon apparent that the right side was pregnant, and that the seeming bag of membranes at the left was the thin and distended septum. As the fœtus passed down through the right os the left os became a mere slit. He was convinced that the uterus was double. The patient made an excellent recovery, although her condition had become very critical from the long-continued vomiting.

DR. MARCY reported the following interesting cases. The first was a young, healthy woman, recently married, who had been under the thoughtful care of a wise physician, himself a member of the family.

The stomach was intolerant to all food. Rectal alimentation had been resorted to, but emaciation had gone on rapidly, followed by alarming symptoms which appeared to seriously threaten life. Pregnancy had advanced to something beyond the third month. The position of the uterus was normal; it was movable and not tender; and the cervix was long and narrow. Forcible dilatation was twice repeated to the os internum to the extent of an inch, without the slightest relief. Abortion was instrumentally induced and was followed by a slow but perfect recovery. So far as known the patient has not since been pregnant.

Case II. The patient, about twenty-five years of age, had been delivered of one child two years previous to present pregnancy. Had always been a strong, healthy, vigorous woman, there being nothing especially noteworthy at the first pregnancy. Vomiting supervened at about the sixth week, and was continuous and persistent until at about the tenth week the exhaustion was extreme. Feeding had been resorted to in fluids repeated at very short intervals, also by rectal alimentation. The uterus was normal, apparently, in its position and development. Its position was changed by a long arched retro-uterine pessary without relief. As in the first instance, life seemed in the greatest danger, and here also the cervix was widely dilated without the slightest avail. Instrumental abortion was followed by a slow but complete recovery. Patient has remained sterile, but well.

Case III. Patient seen in consultation with Dr. Couch, of Somerville, and was in a very weak, exhausted condition. She was a primipara and about thirty years of age, described as being a strong, vigorous woman. Pregnancy at about the third month. Abortion had been advised, but refused as contrary to the rites of the Catholic church. Here dilatation was effected, but entirely without result, and the patient sank from exhaustion and died a few days later.

Dr. Marcy emphasized the importance of not waiting until the patient was in the last extremity, and thinks in the two first cases the recovery would have been much more satisfactory if the abortion had been performed earlier. He criticized the older methods of inducing abortion, with a sound, bougie, tents, etc., as unsatisfactory and dangerous. When necessary it should be done as a surgical aseptic operation. A vagina thoroughly cleansed, the cervical canal rapidly dilated instrumentally, and the uterus emptied at once of its contents. The vaginal track, after contraction of the uterus has occurred, should be carefully protected by iodoform dressing. In this way almost only, can safety from the dangers from hæmorrhage and septicæmia be secured, while the danger from shock would appear to be less under ether with the operation reduced to the minimum of time than when long drawn out through hours of exhausting pain.

DR. WEEKS remarked that he thought many of the sevére cases of vomiting in pregnancy occur in women who do not wish for children. He mentioned a case of a woman who had miscarried three times, once with a blighted ovum. There was excessive vomiting and salivation, followed by deep excoriations of the face. She was treated with great care. Enemata and the usual remedies were used, and a consultation was held. Premature labor was advised. There was a short anterior vaginal wall which probably bound the uterus down somewhat. A bougie was passed into the uterus, and as soon as pains were produced it was removed, and a sponge tent and tampon were inserted. The vomiting did not stop at once, but later the patient did finely.

DR. KELLY, in response to a call from the chairman, made a few remarks on the relation of physiology to the etiology and the therapeutics of the morbid action under discussion. He indicated the scope of his views by instancing Curare, a representative member of the Motor Depressants, as a rational agent in the treatment of those grave cases which at present

demand, as a *dernier ressort*, such a procedure as the induction of abortion, an operation which may well be stigmatized as the opprobrium of the "opprobria of medicine." He consented to enter more fully into the subject at next meeting.

DR. JOHN DIXWELL wished to be recorded as wholly in favor of inducing abortion with due care in all cases of much prolonged and dangerous vomiting of pregnancy, because this method alone, he believes, will as a general rule save the mother's life, and needless suffering, all suggestions or tendencies based on religious views to the contrary. At this time he was attending just such a case.

DR. CHADWICK said that he had been justified in his expectations of obtaining from Dr. Kelly a suggestion at least, of a theory which might bind together the apparently incongruous facts reported so abundantly by others.

Dr. Chadwick had himself got a clue which he hoped might, when followed up, perhaps lead to an explanation of the ordinary nausea and vomiting of pregnancy. In treating patients affected with nervous prostration, by Dr. Weir Mitchell's plan of frequent feeding, he had been early impressed with the immunity from nausea and faintness which resulted from the frequent administration of food. He had immediately adopted the same plan for the relief of the nausea of pregnancy with striking result. The "morning sickness" was almost invariably averted by a late supper and by milk during the night. A friend had recently told him of relief to the same nausea of pregnancy by the chewing of spruce gum. On trial this proved to be true in a number of instances, but not invariably. These two experiences naturally associated themselves together in his mind, but he could find no element of similarity except that in both cases the flow of saliva was promoted. This suggestion received some corroboration from statements that he had recently read in the journals of nausea alternating with salivation. He was loth to accept all these facts as due simply to the chemical effect of the free flow of saliva into the stomach, but was seeking an explanation in some physiological law governing the stimulation of the salivary glands and the stomach by changes in the nerve centres, induced by conditions of the womb.

DR. E. W. CUSHING showed several microscopic preparations of the various septic bacteria, as well as the typhoid bacillus, and the pneumococcus and others, of his own putting up, in explanation of a paper to be read at the next meeting.

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting January 21, 1886.

The order for the evening was a

DISCUSSION ON REFLEX SYMPTOMS IN NASAL AFFECTIONS.

It was opened by DR. E. GRUENING, of the Section on Ophthalmology, who said that in his remarks he could exclude ocular affections resulting from extension of catarrhal processes from the Schneiderian membrane. Having mentioned that hemicrania and asthma had been cured in a considerable number of instances by the removal of sources of irritation in the nasal passages, as reported now by many observers, he remarked that to the ophthalmologist the reflex affections of the nose were of very great interest. The connection between the latter and the eye was intimate, and the relations between the two were reciprocal. Thus, irritation of the nasal mucous membrane frequently produced lachrymation and other eye-symptoms; and in the case of certain irritable eyes, exposure of the organ to a strong light brought on attacks of sneezing. Knowing that ocular symptoms were met with in connection with nasal affections, one might reason *à priori*, if there were no other apparent cause, that the former are dependent on the latter; and if, after appropriate treatment, the eye symptoms still persisted we could conclude *à posteriori*, that such was the case.

In simple cases the instillation of cocaine into the nostrils often afforded a satisfactory test as to whether the ocular trouble was dependent on nasal irritation or not; for if it afforded relief to the eye-symptoms, we might conclude that the latter were to be attributed to the condition present in the nose. Dr. Gruening then related several cases of his own, as examples, in which the eyes were affected for many years in consequence of comparatively mild affections of the nasal mucous membrane, and in spite of the most persevering and skilful treatment directed to the ocular condition; but in which the eye trouble promptly disappeared as soon as the nasal affection was removed by appropriate treatment.

All the cases, however, were not of this simple character, and he then related several in which the reflex eye-symptoms were due to more serious pathological conditions of the nasal cavities. In these also, the eye trouble disappeared as soon as the source of irritation in the nose was removed. In one instance where the patient had suffered for many years, the eyes were permanently cured on the very day that a large mass of hypertrophied tissue was removed from the nose. During the past two years he said he had met with some two hundred cases in which he could refer the ocular symptoms to nasal trouble; but the treatment, which varied according to the circumstances of the case, was not always successful. In most of the unsuccessful cases, however, the patients had disappeared before the treatment was completed, or perhaps even fairly commenced. Still in about one hundred and fifty of the two hundred, complete relief had been afforded by the removal of abnormal conditions of the nasal passages.

Among the symptoms mentioned as most frequent in these cases of reflex eye trouble were: burning and smarting sensations in the eyes, more pronounced in the morning; inability to fix an object in ordinary daylight; irritation and gluing together of the lids; extreme sensitiveness to cold and wind; lachrymation. Other characteristics were: inefficiency of ocular treatment, and efficiency of nasal treatment, even in spite of the absence of nasal symptoms.

DR. THOMAS E. MCBRIDE related five cases which he thought served to illustrate the general subject under discussion. The first was that of a gentleman who consulted him in 1882, for well-marked migraine. The attacks were typical in character, and lasted for about eighteen hours, leaving him completely exhausted. In addition to appropriate hygienic and dietetic measures, he placed the patient on the use of arsenic and extract of cannabis indica. The former he gave up in about six weeks, but the latter he continued, in increasing doses, for fourteen months. By this time

the seizures were less frequent than formerly; but the patient had become disgusted with the cannabis indica, and complained that it made him sick. Indeed, he now suffered from almost constant nausea. In consequence this remedy was withdrawn and he was placed on the use of bromide of sodium, under which the attacks of migraine became less frequent still. While in Europe, however, he consulted Hach, who discovered that he had post-nasal catarrh, and the successful treatment of this completely and permanently cured the migraine.

The second case was that of a boy of eleven, who for several years had suffered greatly from headache, which was always much worse in winter than in summer. It was frontal in character, and it having been discovered that he had nasal catarrh, he was placed under treatment for this, and afterwards had no more headache.

The third case was that of a lady of neurotic antecedents, who was affected with lithæmia, had suffered from neuralgia and headache. The latter was situated in the upper part of the forehead, and extended towards the vertex. She was referred to Dr. Lefferts, who found that she had hypertrophy of the mucous membrane of the inferior turbinated bones; and the appropriate treatment of this condition put an end to her headache and neuralgia.

The fourth case was that of a married lady of fifty, in whom the menopause had taken place at the age of forty. She suffered from hemicrania and hay fever, but was cured by the local treatment of the nasal mucous membrane by a rhinoscopist.

The fifth case was that of a married lady who suffered from difficulty of deglutition and the regurgitation of food into the mouth after it had been swallowed. Four years ago she was treated in Europe for post-nasal catarrh, and had some still. There was undoubtedly gastric catarrh present also. Dr. McBride placed her on the use of iron and arsenic, and applied to the nasal mucous membrane a spray of four per cent. solution of cocaine, with the effect of completely relieving the symptoms mentioned, and thus far there had been no return of them.

DR. B. ROBINSON called attention to the fact that nasal diseases might produce reflex affections of the respiratory and digestive tracts, the genito-urinary apparatus and the cutaneous surface. On the present occasion, however, he said that he would limit his remarks to hay fever and asthma. It was time, he thought, that the designation, hay fever, was given up and that the affection thus called should be given its true name, vaso-motor coryza, as proposed by Dr. John N. McKenzie, of Baltimore. It was a curious fact, however, that the old pollen theory had recently been again brought into prominence by the advocacy of no less an authority than Morrell Mackenzie, of London; though it was no longer accepted by the great mass of observers. Still, pollen undoubtedly acted as an irritant in certain cases. Dr. Robinson then gave a sketch of the researches of Beard, who tried to prove that hay fever was a purely nervous affection, and of Daly, of Pittsburgh, who five years later showed its dependence on local conditions in the nasal cavities. Since then much light has been thrown on the subject by Roe, Sajous, Bosworth, and John N. McKenzie. The nasal trouble present in any case might be either permanent or temporary.

Sometimes cough was dependent on nasal conditions, as, for instance, the presence of a polypus, deviated septum, atrophy, hypertrophy, and chronic rhinitis; but although asthma sometimes occurred in connection with these conditions, they might, of course, exist without giving rise to asthma. In this connection he related the case of a well-known physician of a neighboring city, who suffered greatly from the latter affection. A number of polyps were removed from his nose, but the asthma, which was no doubt dependent on an old bronchial catarrh, still remained. It was not to be forgotten, also, that asthmatic symptoms might be the result of reflex influence from abnormal conditions of other organs, such as the liver, stomach, uterus, and even the spleen. In every case of asthma it was necessary to make a thorough investigation of the cause.

In regard to the nasal mucous membrane, Dr. Robinson said that in all probability, there were areas of special sensibility at times; but his own observations went to show that these were not constant. The sensibility was probably less circumscribed and more general than had been supposed. Apart from any nasal trouble, there must be a special personal tendency, since there were many cases of nasal disease without any resulting reflex conditions.

Cocaine had been recommended as of special service in making the diagnosis of nasal affections, on account, first, of its anæsthetic properties; and second, because it diminished the congestion of the parts. He was convinced, however, that cocaine was not always a successful anæsthetic, especially after it had been used for some time; and that, while its primary effect was to diminish the vascular supply, subsequently, its action was to increase this. Dr. Robinson spoke particularly of the good effects of carbolic acid in the treatment of nasal disease.

DR. W. H. GOODWILLIE exhibited several wax casts of nasal difficulties in which he had operated. One was a case of deviated septum, with exostosis and hypertrophy of the mucous membrane; in another, there was a complete occlusion of the right nostril; and in another, in which the patient was a sufferer from hay fever, there was hypertrophy of the inferior turbinated bones, with dilatation of the pharyngeal orifice of the eustachian tube. In concluding his remarks, he said that the sickness often complained of in these cases of nasal disease, was generally produced by the fœtid secretions which get into the stomach, causing nausea, and interfering with digestion.

DR. SIMON BARUCH thought that this whole subject was entirely too much neglected by the general practitioner, and yet it was one which concerned him almost as much as the specialist, since, in a large number of these cases, there was no very well-defined nasal trouble. Since the publication of Hach's treatise, he had investigated the matter to a considerable extent, having secured a dispensary appointment for the special purpose of obtaining the opportunity of making rhinoscopic examinations, and learning how to treat nasal difficulties. He would, therefore, avail himself of this occasion to briefly relate six cases in which various reflex symptoms were overcome by the use of nasal treatment. One was a case of reflex cough, two were cases of headache, occurring in young girls, one was a case of asthma, and one was a case of severe pain in the right side of the throat, associated with excessive sneezing. In the latter instance, he found enlargement of the lower turbinated bone of the right side, and other nasal troubles, and the treatment adopted

was that by the galvano-cautery. He had also had a number of unsuccessful cases, but to these he would not refer particularly.

He regretted that in the discussion, nothing had been said in regard to the examination and treatment of this class of cases, as it was highly desirable, he thought, that general practitioners should be able to recognize and treat them before they got so bad that it was necessary to send them to the specialist. One of the most frequent conditions present was hypertrophy of the turbinated bones, and in his own experience, he had usually found that this was easy to recognize, while the application of the galvano-cautery, if a good battery was employed, was an easy and efficient method of treatment.

Dr. Henry Schweig said that he must take exceptions to the last remark of the previous speaker. He believed that there was no procedure which required more care and judgment than the use of the galvano-cautery, so that, as a rule, only an experienced specialist was capable of properly applying it. While its judicious employment was very efficient, he felt convinced that the abuse of this method of treatment was much more common than its intelligent use. In order to accomplish the desired end, it was necessary to destroy the cavernous tissue without injuring the secreting surface of the nasal cavity, and the application should always be made from within outwards, instead of the reverse. Unless the greatest care were used, serious and permanent harm would result to the patient, and one very common error was to use too high a degree of heat, a dull red heat being all that was required.

The President, Dr. A. Jacobi, said he would take this opportunity to make some observations in regard to a point to which attention had never hitherto been called, so far as he was aware. For a considerable number of years, he had noted the influence of catarrh, hypertrophy, and other changes in the naso-pharyngeal cavity upon parts of the nervous system, which had not been alluded to in the present discussion. In a large number of children, there were found what are known as peculiar bad habits, such as winking, frowning, drawing up the nose, twitching of the face, and shrugging of the shoulders. He had ascertained, however, that frequently, these nervous phenomena were not due to bad habits at all, and thought, therefore, that any so-called bad habit should be investigated for the purpose of finding out its origin. These cases were not always simple. What was at first a local chorea minor, sometimes resulted eventually, in a general chorea minor. Some twelve years since, his attention had been called by a work published in Bremen, to the fact that hemicrania is sometimes dependent on chronic pharyngitis and amygdalitis; and since then, he had seen hundreds of cases in which this local chorea was associated with conjunctivitis, rhinitis, pharyngitis, enlarged tonsils. In every case of local chorea, he had found chronic nasal catarrh and chronic pharyngitis, and he had never found the nasal trouble without the pharyngitis. In many instances, it was difficult to determine which of the two had been the original affection.

It was well known, he went on to say, that what is known as the third or pharyngeal tonsil, in the back of the fauces, was frequently the cause of retro-pharyngeal abscess; but he believed that inflammation and enlargement of this pharyngeal tonsil was also a common cause of chronic pharyngitis and chronic rhinitis. This also occasioned migraine and hemicrania, and it was evident, therefore, that the whole naso-pharyngeal mucous membrane was capable of giving rise to these reflex nervous symptoms. It was a point of practical importance to know that very often, the treatment of only one small spot was all that was required in a case.

Recent Literature.

A Manual of Auscultation and Percussion. By Austin Flint, M.D., L.L. D., Professor of Principles and Practice of Medicine, and of Clinical Medicine in the Bellevue Hospital Medical College, etc., etc. Fourth edition, thoroughly revised and enlarged. pp. 280. Philadelphia: Lea Brothers & Co. 1885.

This admirable little book is too well known to require any extended notice. That a third and large edition has been exhausted in little more than two years, is evidence that the book is appreciated. We ourselves have used a former edition as a text-book in teaching the physical examination of the chest, and can consequently speak from personal experience. The new edition is improved by the introduction of some plates taken from "Weil's Typographische Percussion," and plates and diagrams illustrating points in cardiac physiology and pathology. We trust that a fifth edition will be demanded as soon as has been a fourth.

A Chart of Physical Signs of Diseases of the Heart and Respiratory Organs. By R. C. M. Page, M. D., Instructor in the New York Polyclinic, etc. New York. 1885.

This chart is printed on a sheet of heavy paper about a foot square, and folds, like a map, between covers three inches by seven. In parallel columns, are set forth the physical signs of the lungs in health, and in the more common diseases to which these organs are subject. With regard to this portion of the chart, we have no special criticism to make. In that portion dealing with the heart, however, we are struck by the entire absence of any allusion to the modification in the size of the heart, which are so important in differentiating functional from organic disease, and the different forms of valvular disease from one another. The characteristic and unfortunate tendency of the student to magnify the importance of a murmur, perhaps the weakest link in the chain of evidence which convicts a valve, is thus encouraged. This is, in itself, a fatal objection to the chart, which, we trust, students will *not* buy. F. C. S.

Inorganic Chemistry. By Edward Frankland, D.C.L., F.R.S., Professor of Chemistry in the Normal School of Science, London; and Francis R. Japp, F.I.C., Assistant Professor of Chemistry in the Normal School of Science, London. With fifty-one illustrations and a plate. Philadelphia: Lea Brothers & Co. 1885.

This volume is an addition to the already long list of text-books on chemistry. We do not believe there is much demand for an additional book of this character, inasmuch as there are several good works on Chemistry from which one may make a choice. It is gratifying, however, to be able to say that this one will take a place among the best of these. It is very complete, and the information contained in it is accurate. Nearly one-fifth of the book is devoted to theoretical chemistry, the remainder to descriptive inorganic chemistry.

Medical and Surgical Journal.

THURSDAY, FEBRUARY 11, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE POLICE AND THE PROFESSION.

ON at least two different occasions, now some months ago, the medical profession of Boston were interviewed by police officers in their efforts to ferret out hidden criminals. In one instance a safe had been blown open and for certain reasons, notably the presence of blood in the vicinity, it was supposed that one of the burglars had been seriously injured. As one means of information the physicians of the city were systematically canvassed by the police to find out what information if any they could give upon the subject, the patrolmen being instructed to interview the doctors on their respective beats. Each doctor was asked if he had been called upon to attend any wounded man during the day.

On a previous occasion when a burglar who was thrown out of a window by the owner of the house which he had feloniously entered, and was known to have had his leg broken by the fall, had escaped the police, disappearing while the humane officer who had discovered him was seeking a suitable conveyance in which to remove him, the physicians were canvassed in a similar manner to know what broken legs they had seen during the day.

Now it is a most ingenious and labor-saving way evidently for the police to gain information, but from the physician's standpoint there is at least a question as to the propriety of resorting to this method. Probably no individuals are more law abiding, as a class, or more inclined to assist in the execution of the laws. We doubt if any objection to answering such questions was made by any of the individuals questioned. Perhaps it was a legitimate method of obtaining information in the cases mentioned, but a question arises whether the method once recognized as a legitimate field of detective research might not lead to unpleasant complications.

It cannot be assumed that every criminal has a right to inflict his confidence upon any doctor he may choose to call and thereby bind that doctor to secrecy. But the communications of patients are in general to be looked upon by the physician as inviolable. The laws of Massachusetts do not regard such communications as privileged and it is therefore the more incumbent upon physicians to maintain the public sentiment which would give them a moral support in refusing to divulge the secrets of their patients.

The objection to the proceedings of the police which we have detailed arises not so much from objections to these particular instances as from the fear of cultivating the idea that physicians may be indiscriminately questioned in regard to their patients.

DISEASES COMMON TO ANIMALS AND MEN.

A FUNDAMENTAL likeness of form, of function and of composition runs through the whole animal kingdom. Anatomically, there is no wide difference between the human frame and that of the higher vertebrate animals, and a marked homology of structure binds all in one grand unity of type. It is well known that Galen and other ancient anatomists learned their anatomy by the dissection of apes. Physiologically, there is no more difference than varying habits of living entail; the biological history of man is, with trifling modications, like that of his brute congener. Histologically, all higher animals are constituted on the same type, and chemically, this is also the case; man lives by assimilating the substance and the forces of the animal, or the proximate principles common to both the animal and the vegetable. Psychologically, it may be argued that the animal has a similar mental, as it has a similar nervous constitution, and what is more remarkable is that certain members of the animal kingdom which seem most unlike man in structure, the bees and the ants, resemble him the most in their psychical traits, as the researches of McCook and Sir John Lubbock go to show.

Pathologically, the likeness also holds good. Pathology being morbid physiology, the disturbances of function in animals and in man are notably similar. Like morbid causes produce like symptoms and like effects in both. Hæmorrhages, overwork, insufficient alimentation, impure air, exposure to excessive heat and cold, mineral or vegetable poisons, viruses have similar consequences in man and in the brute. Hence it is that the diseases of men and animals are the same as far as they are subject to like conditions. Among these diseases, may be specified tuberculous phthisis. This disease, especially prevalent among cattle, (*pommelierè* of the French, bovine phthisis of the English), has been witnessed in all the domestic animals. It is a malady which is almost peculiar to civilized life, and the conditions of faulty hygiene and of contagion (for we are warranted in ranking phthisis in a restricted sense, among the contagious diseases), which engender it in man also produce it in the brute.

Bronchial and other affections due to exposure to cold and wet, are witnessed as well among the lower animals as among men, and the same may be said of the whole category of pulmonary, pleuritic, and peri-

cardial affections. Rheumatism is not uncommon in such animals as the dog and horse, often taking on a chronic and deforming character. There are, besides, certain pseudo-rheumatisms, the result of exhaustive toil, meagre diet, excessive copulation — any one or all of these causes combined — which have been observed in both men and animals, and the jaded horse shares the infirmities of joint and muscle from which his jaded master suffers.

Among the diseases of the nervous system which have been seen in the domestic animals, are, besides the organic and inflammatory diseases of which they occasionally partake in common with man, (meningitis, cerebral abscess, myelitis, etc.), epilepsy, chorea and neuralgia. Megrims have been witnessed in apes, and other pains of a distinctively neuralgic type; chorea is quite frequent in pampered dogs and cats; "fitty" dogs, horses, cats, hares and guinea pigs have been seen by almost everybody. Diseases from indigestion are very common in the domestic animals, especially such as lead an indolent life and are much petted. From all forms of syphilitic disease, the more chaste, exemplary brute animal is fortunately exempt.

Pathological states being essentially the same in men and in animals that most resemble man the outward manifestations or symptoms of these states are similar. Two remarkable instances of this similarity are given by Bouley; the gastric vertigo of horses, and the hallucinations which in animals follow the bite of a mad dog. Between the actions of a dumb animal in the presence of an imaginary foe, and defending himself by his hoofs and horns, and a man in prey to delirium, who also sees his imaginary foes, and flees them or attacks them, there is little perceptible difference.

Among the diseases common to men and animals are certain verminous affections. All fish, all birds, quadrupeds and men are liable to be infested by entozoa; there are more than sixty species that prey on mammals and on man. The similarity of pathological conditions to which all are subject is nowhere better shown than in the history of the various species of tænia, and their relation to the human and animal organisms; it is a subject which is now tolerably well understood, owing to the labors of Davaine, Lenckart, Cobbold and others.

The correspondence between human and animal diseases is especially conspicuous when we compare the diseases of the horse — that domestic animal whose pathology we know the best — with those of man. Any recent work on Veterinary Medicine — that of Jennings for instance — reads very much like a treatise on human pathology, and the therapeutics of both do not much differ. There is hardly an ophthalmologist, moreover, who has not at some time been called upon to treat in the equine quadruped the very kind of eye diseases which he sees daily in his private practice, and it is well known among farriers that cataract is a frequent cause of blindness in this noble animal.

The study of comparative pathology has nowhere been productive of such beneficient results as in the department of epidemic, contagious and infectious diseases, but upon this subject, which constitutes the burning question of pathology of the day, we shall not enter.

ADULTERATION OF FOOD AND DRUGS IN NEW YORK.

A meeting of the New York State Board of Health was held at Albany, February 2d, when an elaborate review of the work of the board during the past year, prepared by the late secretary, Dr. Alfred S. Carroll, was read by Assistant Secretary Carman. Prof. S. A. Lattimore, of the University of Rochester, gave an outline of his investigations of the processes commonly employed in the manufacture of dried fruits as affecting their value and wholesomeness as an article of food. He pointed out the magnitude of this industry, especially in the State of New York, and the importance to the public of the conversion of a perishable and bulky article into a highly condensed product, easily and cheaply transported and capable of indefinite preservation; and showed that the examination of a large number of samples gave no ground of apprehension of danger to the public health. The full text of his report will be embodied in the annual report of the board.

Prof. G. C. Caldwell, of Cornell University, made a report of his work in the department of vegetable alkaloids in the examination of drugs, in which it was stated that in various specimens of citrate of iron and quinine examined there was a considerable departure from the official standard. He submitted a list of the samples purchased in various parts of the State, (very few of which were up to the legal standard), the names of their manufacturers, and the percentage of quinine which they contained.

Professor Tucker reported that since November 1st, he had examined fifty-one samples of drugs and thirty-five of vinegar. Among the former were ammonia, benzoic acid, oxalate of cerium, oxide of zinc, magnesia, chloroform, carbonate of ammonia, and iodoform. Of the fifty-one samples, twenty-five are claimed as good, eighteen as fair, seven as inferior, and one sold by error. The samples of vinegar have shown a great diversity in strength. The highest percentage of absolute acetic acid found was 6.2, and the lowest 2.3; the average percentage being 4.14, while the legal standard is 6 per cent.

A resolution was passed to the effect that the persons making sales of drugs or medicines not up to the proper standard should be notified and ordered to cease their sale. In case of their persisting in the practise after this warning, prosecutions will be instituted. A careful supervision of the manufacture and sales of foods and drugs has become a necessity in every modern State. . . . The temptations to carelessness and sophistication in the preparation of these articles are irresistible, and the consequences may be so serious that some restraint upon the liberty of the citizen is unavoidable.

MEDICAL NOTES.

— "Born to Mr. and Mrs. Martin Haggerty, December 30th, 1885, a daughter, weight eight and one-half pounds. Mother and child doing finely, thanks to Dr. ——, who is destined to become one of our leading physicians." — *Herkimer (N. Y.) Citizen.*

— A despatch to the *Boston Herald*, under date of Montreal, Que., Jan 21, 1886, says that Dr. Trimble, superintendent of the health department, has sent in his resignation to the local board, on the ground that there is not a single case of small-pox in the city, and, so far as known, in the suburbs. There have been no deaths in the latter for some days.

— It is interesting to note that in the nine Prussian Universities during the session 1884–85, 569 doctors and candidates in medicine were examined for the license to practise (*Venia Practicandi*). Of these, 120 presented themselves for the second time, the remaining 449 being new candidates. More than 75 per cent. passed (430), four of these with the mark "very good," 270 with "good," and 156 "satisfactory."

— Another medical journalist has died, Dr. Amédée Dechambre. The death took place from apoplexy, on the 4th ult., in the seventy-fifth year of his age. He was the editor of the *Gazette Hebdomadaire*, and was for many years connected with the Parisian medical press, of which he was the *doyen*. He was also member of the Academy of Medicine, physician to the Council of State, and officer of the Legion of Honor.

—The *Indian Medical Gazette* of December, contains a short account, taken from a Bombay newspaper, of the death of four prisoners in the hospital of the common jail of Bombay, by poisoning. They had been ordered sulphate of cinchonine, but the hospital assistant, Vithul Lingoo, administered strychnine by mistake Death was almost instantaneous. A fifth prisoner who had taken a smaller dose became seriously ill, but his recovery was considered probable.

— An esteemed daily contemporary contains, among its special daily telegraphic hydrophobia telegrams, the following, which is mildly surprising, even after the abundant exercise of the imagination, which the last few weeks of journalistic science have produced. We suppress merely the name of the physician:

ALBANY, N. Y., February 2, 1886. A special from Cohoes says: "George Waterhouse, fourteen years of age, some six years ago, was bitten by a dog in Lansingburg. For the past week, the boy has shown signs of hydrophobia. His condition became alarming, and Dr. ——, of Troy, was called, and administered all the medicines usually used in such cases, but to-night it was deemed advisable to smother him."

— The artists and sculptors of London seem likely to have a good time just now, in perpetuating the outward presentment of some of the leading members of the medical profession. Beside the bust of Sir James Paget, by Boehm, which is commissioned for the Royal College of Surgeons, the *British Medical Journal* hears of projects on foot for testimonial busts or portraits of Sir Henry Pitman, Sir Henry Acland, Professor Humphry, and Professor Redwood.

— A London paper tells of a farmer who picked up a vaccine point which had been left on an apothecary's counter and picked his teeth with it, pricking his gums and effectually vaccinating himself.

— The United States Consul at Hiogo, Japan, reports, that during the month of October last, 1208 cases, and 628 deaths from cholera, were reported in Osaka vicinity, and in Hiogo and Kobe, there were 354 cases, and 227 deaths from cholera, during the same period. During the month of November, there were 58 cases, and 47 deaths from cholera. In the Province of Huelva, the extreme south-western province of Spain, there were, from November 6 to 26, 42 deaths from cholera. In France, the cholera was still prevalent in the Department of Finistere, on December 7, the date of the last consular report. During the twelve days, from November 26 to December 7, inclusive, there were 160 cases, and 62 deaths.

— The *Birmingham Medical Review* is responsible for the following anecdotes of two eminent Scotchmen: The late Professor Syme, of Edinburgh, was not very fond of medical visitors to his wards, in the Royal Infirmary, and did not hesitate to hand them over to his house-surgeon, with little ceremony. Syme was very proud of the number of times he had ligatured the femoral artery. At his death, we believe, he had performed this operation seventy-five times, in all. One day, when showing a Frenchman round his wards, he had occasion to draw his attention to a recent case of this kind, and asked his visitor, with pardonable pride, how many times he thought he had tied that vessel. "Oh! t'ousands!" said the Frenchman, an answer which very speedily sent Syme to his carriage, in no small dudgeon.

— The late Professor Laycock was very fond of drawing attention to hereditary peculiarities. One time, in the middle of a lengthened exposition of the features, in common, of a mother and child, the woman, perhaps, a little uneasy, stopped him, saying, "A weel! I'm no the bairn's mither, I'm just his step-mither."

— Dr. Heywood Smith, who figured in the trial of Editor Stead, of the *Pall-Mall Gazette*, as the physician who examined the girl, Eliza Armstrong, has been reprimanded by the Royal College of Physicians. Dr. Smith sent explanations, and an apology to the College, and the President and Censors in their report upon these communications recommended the adoption of a resolution, that "the College, while acquitting him of deliberate intent to do evil, desires to put on record an opinion that he has committed a grievous error in connection with the Armstrong abduction case, which has brought discredit on himself and the profession to which he belongs. The College, therefore, regards his conduct as deserving the severest censure, and requests the President to express the views of the College, and to reprimand him accordingly." The President accordingly addressed to Dr. Heywood Smith a severe reprimand, and warned him to be careful as to his conduct in the future.

— It is said that the teeth of all children attending the communal schools in Brussels are examined by order of the State, and during the year 1882–83, no fewer than 1,250 pupils required the services of the dentists. The managers of the North Surrey District School, Anerley, England, have appointed a dentist to attend weekly, in order that the children may have proper attention paid to their teeth.

— There have been recently abundant subscriptions to Lady Dufferin's Fund for providing the women of India with female medical aid.

— We learn from the *Lancet* that at the Birmingham Police Court, recently, summonses were taken out by the Inland Revenue against a shopkeeper for selling, and against a firm of manufacturers for supplying, certain drinks, under the name of temperance wines, which were alleged to be intoxicating. An analyst to Somerset House gave evidence that the port wine was a fermented liquid containing 17.4 per cent. of proof spirit; the sherry was a liquid of the same description, and contained 19.6 per cent. of proof spirit: thus showing that a large proportion of alcohol was hidden under the seductive title with which the bottles were labelled. Another compound of a similar kind was sold under the name of "hot Tom," the purpose of which was to give a spiced flavor when added to beer. It was suggested for the defence that fermentation must have occurred after the wines had been bottled; but the absence of carbonic acid in any quantity, proved that this could not have been so. The salesman was fined 1*s.* and costs, the manufacturers £10 — a penalty which, our contemporary thinks, will probably stop the sale of this particular form of refreshment, but which will be of more service in calling the attention of teetotalers to the nature of the trade in powerful stimulants sold under tempting and unsuspecting names.

Miscellany.

A CASE OF ULCERATIVE ENDOCARDITIS.

PROFESSOR PURSER made a communication to the Academy of Medicine, in Ireland, (*Dublin Medical Journal*, January, 1886), upon a case of ulcerative endocarditis, the second he had seen. The patient, a man aged twenty-two, had had rheumatic fever three or four years previously, and had lately been very intemperate as to strong drink. On admission to hospital, he was delirious, very violent, temperature 104°, pulse regular and strong, complained of pain in his head and ears. His heart and lungs were carefully examined and found normal. The only lesion visible on his person was a small, recent scar on one knuckle, surrounded by loosened epidermis, as if a pustule had been present, which had burst before admission. There was no glandular enlargement in the arm, nor anything abnormal in its veins or lymphatics. On October 24th, a careful examination could detect nothing abnormal in either heart or lungs, but on the next day, Professor Purser discoverd a loud systolic valvular bruit, which had certainly not been present on the 24th. This determined him to the diagnosis of ulcerative endocarditis — a diagnosis which the subsequent *post-mortem* completely established. The delirium and fever continued without much intermission till his death, which was preceded by œdema of the lungs, the bruit continuing all through. At the autopsy, hæmorrhages were found in the brain, lungs, spleen, kidneys, intestines, and the retinæ. The heart and its valves were practically healthy, with the exception of the mitral valve, whose posterior curtain was ulcerated and completely disorganized, the surface of the ulcer being ragged, and covered with a diphtheritic-like deposit.

The microscope showed that this diphtheritic deposit, as well as the innumerable small hæmorrhages in the various organs (except those in the lungs, in which no micrococci could be detected), were caused by masses of micrococci, many beautiful specimens being shown at the meeting, where the vessels were visibly plugged by micrococci. Professor Purser could find no other door of entrance into the body for the micrococci in this case than the small patch of abrasion on the knuckle. In the former case he had seen, there had been suppuration of one of the vesiculæ seminales.

A NEW SOURCE OF QUININE.

IT is not generally known that the present cheapness of quinine is, in great part, due to the discovery of a quinine-yielding bark in a plant, which is not one of the cinchonas. We learn from the *Indian Medical Gazette* that *Cuprea* bark contains quinine, and as the plants grow readily near the coast, it can be cultivated and the bark exported at very much less cost than cinchona bark, which has to be carried from the hills to long distances at great expense. There are several varieties of *Cuprea* bark. "New Remedies," No. 8, p. 41, gives the following particulars regarding two of these varieties. *Remijia pedunculata* contains quinine and homoquinine, while *Remijia purdieana* contains little or no quinine, but an alkaloid, which has been named cinchona by its discoverer, M. Arnaud. Homoquinine is a double alkaloid, as shown by Messrs. Paol and Counley (*Pharm. Journ.*, March 7th, 1885, p. 730). It can be split up into quinine, and another alkaloid known as *Cupreine*, in the proportions of about one of the former to two of the latter. Homoquinine forms a sulphate less soluble than that of sulphate of quinine, which apparently shows that it has entered into the commercial quinine, made from *Cuprea* bark, until a short time ago, when a mode of separating it from quinine, was discovered.

Dr. King, the Superintendent of the Bengal Government, Cinchona Plantations, in his Annual Report for 1884–1885, says that *Cuprea* bark has been poured into the London market in very large quantities. It is not very rich in quinine, but its quinine is easily extracted; and, being produced near the coast, it has been possible to put this bark upon the home market at a small cost, and thus, to a large extent, to oust the cinchona barks which had been exclusively used in quinine manufacture. Some seed obtained from South America was planted in Sikkim by Dr. King, but although forty seedlings were raised, they were not very vigorous, and it is thought that the climate of Sikkim is not well suited to them.

CITY AND SUBURBAN RAPID TRANSIT FROM A SANITARY POINT OF VIEW.

THE *Sanitary Engineer*, in its issue for January 28, discusses this subject. After mentioning the desiderata for passenger traffic, as comfort for the patrons, rapidity of transit, a minimum of annoyance to non-travellers, and low cost, it condemns all existing methods which involve the use of land which is employed for other purposes, as public streets, and of elevated and tunnel roads. It says: "It is certain that the requirements of rapid transit are not fulfilled by railroads on the surface of the ground, on which heavy motors, noisy in their operation, run at high speed, as they do in the suburbs of Boston, New York and Philadelphia. They are not fulfilled by passenger-cars, heated by coal-stoves, and swept by a draught of cold air from a tilting transom over the end door, as is the barbarous custom on the Pennsylvania and Hudson River Railroads. They are not fulfilled by iron-trestles built over public streets and too flimsily constructed to carry motors of sufficient power to draw the necessary loads, and yet carrying machines which are so noisy in their operation as to be a frightful nuisance. Still less can the necessary condition of comfort and health be fulfilled by any subterranean structure, such as is suggested for Broadway. In London, where underground roads have been built and operated for several years, with all the efforts of the ablest men, theoretical and practical, to attain perfection, the testimony of the builders and managers of the roads is very strong to the effect that all their efforts to secure good ventilation have proved unsuccessful. In New York the discomfort of underground travel is abundantly proven to the thousands who pass daily through the tunnels and covered ways of the Fourth Avenue road from Thirty-fourth to Forty-first Streets, and from Fiftieth to Ninety-sixth Streets."

It continues: "We believe that the day is rapidly approaching when large cities will be traversed by viaducts, constructed on property exclusively dedicated to that purpose, and on which trains of cars will be propelled at high speed through the open air by nearly noiseless motors, two tracks being devoted to long distance and two to short distance travel. . . .

"What the advance of science may produce in the way of motive power is, of course, unknown, but in the present state of mechanical science the most probable solution of the problem of rapid transit for cities lies in elevated viaducts for trunk lines of fast travel with compressed air or electric motors, cable tramways for lines concentrating at centres of transfer to the trunk lines, and horse or compressed-air tramways for collectors in outlying, sparsely settled districts. The health and safety of the public, which are the 'supreme law,' demand the prohibition of grade crossings where rapid motors run, and the keeping of the passengers above ground at any cost."

Correspondence.

LETTER FROM VIENNA.

VIENNA, December 8, 1885.

MR. EDITOR, — As many young physicians are undecided as to their plan of study when they leave for Europe some may be interested to read about the experiences of a fellow-student from America and myself on our arrival here.

We decided to spend several months in the study of German before attempting to do much work in medicine, and therefore on the first of March settled down in Würzburg.

Würzburg is a quiet little city in the Northern part of Bavaria, once a place of great importance, but now known only for the University and its choice "Stein-wein." It is full of quaint old houses, and its narrow winding streets afford an ever varying pleasure to one interested in the architecture of the sixteenth or seventeenth centuries. On the site of the old wall and moat is now a charming park, bordered by fine new houses. The environs are pretty, giving an opportunity for many pleasant walks.

Bavaria is not a good place to study classical "Hoch Deutsch," as the pronunciation is bad, but for a medical man it is better to learn the pronunciation and dialect of South Germany, rather than the pure German of Hannover, as he is then better able to understand the lectures of Vienna. We have found no difficulty in understanding the so-called Vienna dialect, and such is not the usual experience of men who have studied in North Germany.

There are very few English in Würzburg, and none whom a medical student would be apt to meet. We had no difficulty in finding good German teachers.

As to the medical advantages there, they are good; they have a hospital of some six hundred beds, fine university buildings and many professors of great celebrity. The lectures of the summer Semester, began about the first of May, and by that time we were able to profit by them both from a medical and from a German point of view. Rindfleisch is the most charming lecturer I ever heard: he lectures to his class as if he were holding an animated conversation with a knot of friends.

On the first of July I went to Prague to attend a course given by the first assistant in the lying-in hospital there. The course is essentially a touch course, but aside from that the students are invited to make the daily visit in the wards; students are not allowed to operate. I will give a short sketch of their methods, some of which were new to me. When the labor first comes on, before examination, the woman is given a vaginal douche of corrosive sublimate (1–2000). If the case runs a normal course, this is the first, last and only douche given.

The chief exceptions to this rule are the following: —

(1) When gonorrhœa is present.

(2) If the lochia become foul. In such cases a douche of three per cent. carbolic acid is given twice daily.

(3) If the lochia become very abundant in the latter part of the second week. In this case a douche of alum and acetate of lead is used. The advantages claimed for this method are essentially three. The avoidance of possible infection from unclean instruments. The prevention of admission of atmospheric air. The smaller amount of the lochia.

During the puerperal period the external genitals are washed twice daily with corrosive sublimate (1–2000) and all abrasions *lightly* dusted with iodoform. The napkins are sublimated absorbent cotton.

As to their results, in 774 deliveries five women died: one of double pneumonia; two of rupture of the uterus; one of cerebral hæmorrhage; one of acute endometritis and acute nephritis.

In Munich, Berlin and Vienna the vaginal douche has been abandoned in all normal puerperal cases. Schroeder, in the last edition of his work, does not even mention the use of a vaginal douche in his chapter on the care of puerperal women. In Prague the corrosive sublimate (1–2000) is used as the antiseptic for the hands of operators.

During the last year the policy of non-interference in the processes of nature has been applied in the care of the children. Their mouths are never washed out; since the introduction of this method thrush has become as rare as it formerly was frequent. I saw three cases in Prague; they all occurred in the wards of a new nurse; when the assistant complained, she said, "I assure you that I wash

the mouths with the greatest care every time the babies suck."

As yet Professor Breisky has not published the results of this expectant method of treatment.

Yours very truly, HENRY JACKSON, M.D.

HUMANIZED VIRUS, ONCE MORE.

OFFICE SUPERINTENDENT OF HEALTH,
PROVIDENCE, JAN. 30, 1886.

MR. EDITOR,— Once more I ask permission to use your columns to reply to Dr. Martin. His last communication is mainly a reiteration of his former assertion that we are not using long humanized virus in Providence. This statement he makes simply on the ground that the symptoms produced by this virus are not those which he thinks ought to be produced by long humanized virus and are not like those produced by the long humanized virus in use in England. But the question is not one of theory, or of English practice, but one of fact as to what virus we use in Providence. In this office are books in which a record is kept of all vaccinations done by the department. In these books the pedigree of our virus can be traced back continuously from person to person to February 29, 1868. During this period there were two hundred and seventeen transmissions. This record was made by Drs. Chas. H. Leonard and Edwin M. Snow, physicians of high repute and unquestionable integrity. Every one will admit that this is sufficient to permit the application of the adjectives "long humanized" to this virus. But furthermore, perfect reliance may be placed upon the statement of Dr. J. W. C. Ely, who was public vaccinator from 1856 to 1868, that during this time the virus was propagated in a continuous series without being renewed from the cow. Dr. Martin very kindly assumes that I am merely in error in this matter. But there can be no ground for mistake; either this virus has a human pedigree of almost thirty years, or else I and the gentlemen referred to have deliberately falsified the record.

I have no doubt that bovine virus is perfectly competent to protect against variola. All I claim is that the stock of humanized virus maintained in this city is equally protective. There are certain advantages in the use of bovine virus, provided it is properly prepared. The danger comes from making it an article of commerce. I believe that it may be a wise procedure for Health Officers, either municipal or state, to prepare and distribute this virus, or at least to strictly supervise its preparation. We thus far have obtained better results with our own humanized virus than with any bovine virus which we could purchase. Certainly the confidence of the medical profession in the producers of bovine virus is not strengthened, when one of these producers, who is inclined to claim for himself somewhat of a monopoly of scientific knowledge and accuracy, coolly repudiates without any investigation, certain facts which do not coincide with the assumed theories upon which his business so largely depends.

I trust that the written proof which I am ready to present to any one interested will be sufficient to close this controversy which was begun by the unfounded assertions and gratuitous assumptions of Dr. Martin.

Yours truly, CHARLES V. CHAPIN, M.D.

[The Editor begs to express the hope that this question may be considered closed with the present communication. ED.]

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 30, 1886.

Deaths reported 2,019: under five years of age 656; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 284, lung diseases 321, consumption 303, diphtheria and croup 124, scarlet fever 31, typhoid fever 25, diarrhœal diseases 36, whooping-cough 24, cerebro-spinal meningitis 16, malarial fever 11, puerperal fever seven, erysipelas five, measles four, small-pox one. From diarrhœal diseases, New York 13, Cincinnati five, Boston four, Philadelphia, Baltimore and New Orleans three each, Cambridge two, Providence, Charleston and Malden one each. From whooping-cough, New York 17, District of Columbia two, Philadelphia, Cincinnati and Providence one each. From cerebro-spinal meningitis, New York, Philadelphia, Boston, Cincinnati, Taunton two each. From malarial fever, New York five, New Orleans three, Philadelphia, Boston and Baltimore one each. From puerperal fever, Philadelphia two, New York, Baltimore, Cincinnati, Taunton and Brockton one each. From measles, Baltimore two, New York and Philadelphia one each. From small-pox New York one.

In 107 cities and towns of Massachusetts, with a population of 1,278,411 (population of the State 1,941,465), the total death-rate for the week was 16.59 against 18.23 and 17.16 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending January 16th the death-rate was 23.8. Deaths reported 4,149: infants under one year of age 935; acute diseases of the respiratory organs (London) 534, whooping-cough 156, measles 111, scarlet fever 46, fever 41, diphtheria 39, diarrhœal 37, small-pox (Liverpool two, London, Manchester and Cardiff one each) five.

The death-rates ranged from 17.2 in Sunderland to 32.7 in Halifax; Birkenhead 19.1; Birmingham 23.4; Bradford 21.2; Hull 17.2; Leeds 24.2; Leicester 20.9; London 23.9; Liverpool 23.8; Manchester 30.6; Nottingham 26.1; Sheffield 18.6.

In Edinburgh 22.1; Glasgow 26.6; Dublin 33.3.

For the week ending January 16th in the Swiss towns, there were 47 deaths from consumption, lung diseases 41, diarrhœal diseases 11, diphtheria and croup seven, whooping-cough four, erysipelas one.

The death-rates were: at Geneva 25.2; Basle 18.5; Berne 24.6.

The meteorological record for week ending January 30, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Jan. 30, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 30, 1886, TO FEBRUARY 5, 1886.

VICKERY, RICHARD S., surgeon and major. Assigned to duty in connection with the Army and Navy Hospital at Hot Springs, Ark. S. O. 24, A. G. O., January 29, 1886.

CHAPIN, A. R., first lieutenant and assistant surgeon. Relieved from temporary duty at Fort Robinson, Neb., and ordered to resume his proper station, Ft. Laramie, Wyo. S. O. No. 11, Department of the Platte, February 2, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING FEBRUARY 6, 1886.

BABIN, H. J., surgeon. Ordered to United States Steamship "Vandalia."

DIXON, W. S., surgeon. Ordered to Marine Rendezvous, New York, to relieve Surgeon Babin.

WHITING, ROBERT, passed assistant surgeon. Ordered to United States Steamship "Vandalia."

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. OBSTETRIC AND GYNÆCOLOGICAL SECTION. — There will be a meeting of this Section at the large Medical Library Room, 19 Boylston Place, on Wednesday evening, February 17th, at 8 o'clock. Communications: Dr. W. H. Baker, "Report of Ten Cases of Uterine Cancer where a Radical Operation was done Four Years and More ago." Dr. A. P. Weeks, "Acute Inversion of the Uterus." Refreshments after the meeting.

JAMES R. CHADWICK, M.D., *Chairman.*
ROBERT B. DIXON, M.D., *Secretary.*

APPOINTMENTS AT THE BOSTON DISPENSARY.

At the January meeting of the managers of the Boston Dispensary Dr. George G. Hayward was appointed physician to the department of diseases of women; Dr. Edward W. Warren physician to the department for diseases of the throat and nose; and Drs. Hayward W. Cushing and Gardner W. Allen physicians to the department for diseases of the genito-urinary system.

An orthopædic department was established and placed in charge of Drs. Royal Whitman and William M. Conant.

Drs. Herbert B. Whitney, Howard M. Buck, and George E. Richards were appointed district physicians.

BOOKS AND PAMPHLETS RECEIVED.

The Climatic Treatment of Disease, Western North Carolina as a Health Resort. By Henry O. Marcy, A.M., M.D. (Reprint from the Journal of the American Medical Association, December 26, 1885.)

Hunterian Lectures on some of the Injuries and Diseases of the Neck and Head, the Genito-Urinary Organs and the Rectum. Delivered before the Royal College of Surgeons of England, June, 1885. By Edward Lund, F.R.C.S. London: J. & A. Churchill. 1886.

Rome in Winter and the Tuscan Hills in Summer. A Contribution to the Climate of Italy. By David Young, M.D., etc. London: H. K. Lewis. 1886.

Medico-Chirurgical Transactions. Published by the Royal Medical and Chirurgical Society of London. Second Series, Volume the Fiftieth. London: Longmans, Green & Co. 1885.

Bright's Disease of the Kidneys. By R. C. M. Page, M.D., Instructor in Diseases of the Heart and Lungs and General Medicine, New York Polyclinic. (Reprint from Medical Record, November 21 and 28, 1885.)

Circulars of Information of the Bureau of Education. No. 3. 1885. A Review of the Reports of the Royal Commissioners of Technical Education, etc. By the late Charles O. Thompson, A.M. Ph. D. Washington: Government Printing Office, 1885.

The Principles and Practice of Medicine. By Charles Hilton Fagge, M.D., F.R.C.P., etc. Including a Section on Cutaneous Diseases by P. H. Pye-Smith, M.D. Chapters on Cardiac Diseases by Samuel Wilks, M.D., and complete Indexes by Robert Edmund Carrington, M.D. Vol. II. Philadelphia: P. Blakiston, Son & Co. 1886.

Seventh Annual Report of the State Board of Health of Illinois, with an Appendix. Springfield, Ill. H. W. Rokker, State Printer and Binder. 1885.

Original Articles.

CASES OF EPILEPSY TREATED WITH BORAX.[1]

BY CHARLES F. FOLSOM, M.D.,

Visiting Physician for Nervous Diseases, Boston City Hospital.

ALTHOUGH there are many remedies suggested for the treatment of epilepsy, the number from which any permanent benefit is derived is exceedingly small — so small, that probably few physicians think of prescribing anything but some of the preparations of the bromides, unless they have already been tried and failed. It is true that some benefit is the usual result of the use of the bromides, often marked improvement, sometimes cures. But their use is attended with disadvantages, if given in sufficient quantity to control the attacks, in the vast majority of cases; and with certain individuals, these common uncomfortable symptoms are so excessive as to make the bromides, when taken for a long time, a greater source of annoyance than the convulsions themselves. There are some cases, also, in which no benefit is derived from the bromides in any possible combination of their salts, or whether with ergot, belladonna, ammonia, and other drugs, or alone; it now and then happens that they make the disease worse, and exceptionally, they give rise to maniacal symptoms. It is not seldom that they cannot be used.

Their common effect is to impair appetite, interfere with digestion, and produce a certain amount of mental and physical sluggishness, which may amount to a settled gloom and indisposition to effort, and which is generally attended with some loss of flesh, even if not great, unless some tonics are given, or special efforts are made to keep up the general health; and, if given to the extent of controlling the convulsions, the bromidism produced is often so disagreeable to the patient, that other remedies must be sought for. The list of drugs which have been tried in such cases is long. To-night, I desire to call attention to a single one, borax, which has been prescribed in a few cases at the Hospital for Epileptics and Paralytics in London, and which I have used, more or less, for three years.

CASE I. Miss ——, age, twenty, to whom I was called about midnight of May 6th, 1883, with the statement that she had, thus far in the night, had three violent epileptic attacks. She was of fine figure and good general health, without ascertainable hereditary predisposition to disease. She had the usual diseases of childhood in mild form, and had given great attention to her health, so that her appearance generally, if not under the influence of drugs, would be that of perfect health. She had never had convulsions in childhood or infancy. At the age of nine, she caught her foot in such a way as to be suspended head downwards for a time, the approximate length of which I could not learn, until her cries brought some workmen to her relief. She had soon after, that is, in the middle of the summer, a few attacks of petit mal, extremely slight, of which she was aware, and during which she did not entirely lose consciousness. In the following winter, she had epileptic convulsions, for which her parents consulted Dr. Brown-Sequard, who gave her his usual prescription of the bromides, probably with potassium iodide and carbonate of ammonia. She improved for a number of months, although the convulsions did not cease, until December 8th, 1874, when she had not had an attack for five months. She had others on the 23d and 27th of the same month. Although she was quite under the influence of the drug, the convulsions became frequent, and its use was finally abandoned for the time being. Since that time, she has been under the care of many physicians, among whose names I mention those of Dr. Webber and Dr. J. J. Putnam, of this city, in order to give assurance that every therapeutic measure offering any probability of success had been faithfully tried. The bromides and oxide of zinc were the only drugs which materially diminished the frequency of the attacks, but both had to be used in such quantity as to produce a very distressing debility, with only the result of making the number of attacks fewer, but not of causing them to cease.

The number of epileptic convulsions for the several years was as follows: 1875, twenty-seven; 1876, eighteen; 1877, ten; 1878, eleven; 1879, eight; 1880, twenty-seven; 1881, ten; 1882, seven; in 1883, the first attack was on the 23d of January. In February, having thought that they had exhausted the resources of the medical profession, the parents got some advertised medicine, Turner's, from New York, and began giving it, with the result that there was no convulsions that month. In March, there were two, in April, three; in May, one, on the first day of the month, and three on the sixth, when I was called to see the patient. So far as known, no attacks occurred during sleep.

I found, on analysis of the drug by the State Board of Health, that my patient had been taking a large quantity daily, of bromide of potassium. She was so bromidized as to stagger in walking, to have hallucinations of sight, and to be so dull mentally as almost to suggest primary dementia.

The improvement of the general health seemed the first and imperative indication, so that I stopped all medicines and sent her to the seashore, with the result that there were twenty-five attacks in the next seventy-eight days. At the end of that time, namely, August 1st, with cod liver oil, malt, and fresh air, she had regained the appearance of health, and I began giving her ten grains of borax, three times a day. There was no attack until the 15th of the month, when I increased the quantity to fifteen grains. The only attacks in 1884 were two, one May 10th, and one December 22d. In 1885, there were three, namely, in March 28th, April 19th, and September 5th, when the borax was increased to twenty grains, three times a day. Thus far, there have been two this year, but I think that they were due to a serious disorder of the digestive organs, and that they might have been prevented had I been called in time.

So far as the convulsions are concerned, the use of the borax has been attended with success far beyond any other drug. In other ways, however, the improvement has been much greater. The attacks of petit mal, which formerly were, at times, incessant, frequently counting up several dozen a day and twenty in a single hour, are now very seldom a source of annoyance, and never frequent. But most of all, the general health is perfect, and the young lady has been able, for the first time in a dozen years, to enter into the pleasures and duties of social life pretty much as she would like, with certain precautions which are not onerous, and her old-time cheerfulness and bloom have returned.

[1] Read before the Boston Society for Medical Improvement, February 8, 1886.

The only annoyance from the use of the borax in this case, has been a dry, scaly eruption, giving rise to a great deal of itching, but which disappeared after several week's use of arsenic internally, and oxine of zinc ointment, with vaseline, externally. Aromatic tinctures given with it prevented the nausea, which immediately followed taking it with only water.

CASE II. March 28th, 1884. Miss ——, age, twenty-six, without hereditary predisposition to disease. In infancy, the left side was accidentally observed to have become of less power than the right. Just when this happened, and under what circumstances, I could not learn, and evidence of it is still seen in the lessened size of left leg, trunk, and arm, noticeable on measurement and inspection, but not observed casually.

In the fourth year of age, there were several convulsions, then attributed to teething; also one very mild when ten years old, and another more severe in 1871, when menstruation began. Soon after, there were attacks of petit mal, of which there was no record until 1873, and since then, of course, some have failed to be observed, but all the attacks attended with decided loss of consciousness are thought to have been seen and noted as in the following table, the number of attacks of petit mal being indicated in roman figures, the others in italic.

The effect of the bromides may be seen in the reduced number of severe attacks for a few years after 1873, but the attacks of petit mal rapidly increased, and, after 1877, the others began to increase somewhat, although the patient was constantly bromidized to a slight extent. In August, 1883, the bromides were stopped for about three weeks, with four convulsions in that time, as had happened in giving them up twice before. The patient, at the close of March, 1884, had a very severe convulsion, and was, at that time, thin, pale, dull, not interested in anything, inclined to be silent and gloomy, with periods lasting several days at a time, during which she was much depressed, and frequently weeping. She had every advantage of travel, frequent change of scene, driving, etc., but the outlook seemed hopeless enough in depression in health and spirits if she continued the bromides, more frequent severe epileptic convulsions, if she gave them up.

Just after the attack in March, 1884, and just before that in April, borax was commenced, and the bromides were discontinued. In the latter part of July, the borax was omitted on account of a very troublesome itching, scaly eruption, which, however, afterwards disappeared with the use of arsenic and ointment, as in the last case. In the meantime, there were three convulsions, and the borax was resumed. From March, 1884, to the present time, twenty-two months, there have been only two attacks while the patient was under the influence of the borax.

Something, therefore, has been gained, as compared with the bromides, in the manifestations of the epilepsy, but the general condition of the patient has generally improved. She has gained eleven pounds in weight, her general appearance is that of health, and she is uniformly bright, cheerful, and interested, with fifteen grains of borax, three times a day.

An intense itching comes on every several weeks, which disappears in two or three days, by taking seven drops of Fowler's solution three times a day, but which, without that, continues until a troublesome, dry, scaly eruption appears.

In both cases, the general condition had been wretched for years, from the prolonged use of the bromides, and as to the diminished frequency of the convulsions, all that could be said was that something was gained by taking the medicine. In my desire to build up the general health, and keeping in view the tendency to an annoying skin disease from the use of borax, it is quite possible that I have not increased the dose rapidly enough. It is my intention to gradually reach thirty grains, three times a day, if there is no contra-indication to its use. I should say that, in both cases, the usual physical examinations were made of chest, urine, eyes, etc. The result was negative as to evidence of organic disease. In both cases, also, there were the usual restrictions as to diet and habits of life. Indeed, there had been, for years, the care exercised in these respects, which is common with physicians who have given especial attention to the treatment of epilepsy.

I have a number of other cases in my note-books, of marked improvement from the prescribing of borax after the bromides had failed to do much good, and also, many where the alternate use of the two drugs, each for several months, was attended with excellent results. But it would be superfluous to report them in detail, and tiresome to listen to them. I have seen only one apparent cure from the use of borax, but thus far, I have used it only in cases where the prognosis seemed very unfavorable.

The first few doses of borax often produce diarrhœa, which soon ceases. The eruption on the skin is readily controlled, and the tendency to nausea, flatulence, or indigestion, is easily met with spirits of chloroform, tincture of cardamon, compound spirits of lavender, etc.

In a disease where the natural tendency is to mental

impairment, as in epilepsy, it is difficult to prove that the long continued use of the bromides tends towards dementia of even a slight degree, but I believe that they cannot be used for a long time without some disadvantage, and that in children or youth, they cannot be taken for years together, to a sufficient extent to control epileptic convulsions without not only direct injury to the brain, but also, without producing an arrest of development due to lessened energy and diminished use. I have no doubt, however, that there are cases where it is well to give them, nevertheless, and I cannot say how often, or in what cases, borax will prove successful. But we should not abate our zeal in trying to find some other means for the same end, with which there may not be so manifest injury with the benefit.

ON THE LIMITATION OF THE CONTAGIOUS STAGE OF SYPHILIS ESPECIALLY IN ITS RELATIONS TO MARRIAGE.[1]

BY FESSENDEN N. OTIS, M.D., OF NEW YORK.

In whatever consists the true contagium of syphilis, one important fact in relation to it is well proven, namely: that it is contained in the substance of the initial lesion of chancre and the lymph channels and glands in immediate relation thereto. And that, as a rule, for a period of at least eight weeks, it is confined between this point and the general blood current.

It will thus be seen that the doctrine of a mysterious, instantaneous, syphilitic infection, as still claimed by some authorities, is denied, and that a gradual infection, through physiological channels alone can be considered possible.

A few words in proof of this position. Inoculations of healthy persons with the blood of a person affected with an initial lesion of syphilis failed to communicate syphilis, until after the eighth week from the date of infection. Several well authenticated cases of this sort have come to my knowledge. Twice the inoculation was in my own person. A great amount of evidence on this point is furnished by Diday. In his work on Infantile Syphilis he says, that syphilis contracted by the mother after the completion of the seventh month of gestation *has never produced the disease in the fœtus.* Abernethy had previously claimed the same immunity for the fœtus, after the seventh month, but Diday asserted it as a *law* to which there were practically no exceptions. On page 32 of his work on Infantile Syphilis (Sydenham edition, 1859), he says: "Under similar circumstances a child born, apparently healthy, of a woman who had contracted syphilis in the eighth or ninth month only, might be entrusted to a healthy nurse without fear of communicating the disease to her."

Practically, as it is thus shown, the disease is limited to the initial lesion and its immediate vicinity during the first two months after infection. Syphilis may then, up to such period, be claimed as a local and not a constitutional disease.

It has been proven and accepted by such authorities as Fournier and Cornil of Paris, Mireur, of Marseilles, Van Buren and Keyes and Bumstead and Taylor, of New York, Hill and Cooper, of London, and others, that the physiological secretions, mucus, milk, tears, sweat, sebum, urine, semen, etc., do not contain the contagium of syphilis. Fournier says: "It has long since been established that the semen of a syphilitic subject is not susceptible of transmitting syphilis."[2]

Bumstead and Taylor say, (Fifth Edition, page 463): "The non-inoculability of the semen of syphilitics was fully proven in a number of experiments made by Mireur, of Marseilles"; and further at page 807, "It has been proved that the semen is not an infecting fluid, as are syphilitic blood and the secretion of specific lesions. . . . We therefore cannot admit the infectious properties of semen as regards the female or the fœtus subsequent to conception." Hill and Cooper (Second Edition, page 73) say: "The semen cannot be asserted to be contagious with the knowledge we at present possess." Cornil, 1882, says: (Am. Edition, page 351) "There are no reliable cases evincing the truth of syphilitic contagion by the spermatic fluid." Acceptance of this important fact enables us to eliminate from the mysteries of syphilitic contagion such cases as those where the father is claimed to have infected the embryo or fœtus, while the mother has escaped the disease, and also makes its clear beyond dispute that syphilis is never, under any conceivable circumstances, communicated from the father directly to the fœtus, but that in order to infect the product of conception before birth the mother must first be infected.[3] The semen having been proven not to contain the contagium of syphilis, settles this much discussed question, inasmuch as through the semen alone has the father any possible access to the ovum of the fœtus.

It will also be seen that if the physiological secretions which do not contain germinal cells, are free from the contagium of syphilis, this constitutes a strong argument in favor of the nature of the contagium of syphilis as claimed. And further, if contact of a degraded germinal cell is essential to the production of syphilis and the disease is conveyed to the embryo or fœtus only through the blood of the mother, there is then no longer, strictly speaking, any *hereditary* transmission of syphilis. In order to the acquirement of syphilis an organism free from that disease is essential. The infecting cell of syphilis must first be brought in contact with otherwise healthy cell material. "No mysterious hereditary influence is necessary nor can be admitted. If the disease germ of syphilis, by contact with external parts or through its amœboid power, traversing tissue, reaches healthy cell material, whether in the adult, the infant or the embryo, then the syphilitic influence is directly transmitted and its development must be governed by the same laws that characterize its progress in the known behavior of the disease in the adult; modified to a greater or less extent by the age and degree of stability of the tissues in which the disease is developed. . . . It is undoubtedly the fact that various adynamic diseases and conditions in fœtal and infantile life result from pre-existing disease in the generative organs of parents who have been subjects of syphilis, but that any syphilitic disease, proven to be such by its power to transmit syphilis, has been communicated to healthy persons after the active or so-called *secondary* stage of the disease has passed, there is no well authenticated evidence to prove."

[1] Read before the New York State Medical Society. Some introductory paragraphs on the nature of the syphilitic contagium have been necessarily omitted.

[2] Alfred Fournier, Syphilis et Mariage, Paris, 1880, page 26.

[3] It is important to note that the very authorities which claim that the embryo or the fœtus may be affected while the mother escapes still advocate the administration of mercury to the mother, and they also claim distinctly that such treatment prevents subsequent abortions and disease in the fœtus.

I am quite aware that this position will at first be received with surprise, but it is the logical sequence of the acceptance of the degraded human germinal cell as the true contagium of syphilis, and it can, I believe, be shown to be in the fullest accord with all well authenticated facts in regard to hereditary syphilis.

These views were originally published by me in a series of class-room lessons in 1879, and again in my volume on the "Physiological Pathology of Syphilis," in 1881, and elaborated more fully in an article on the "Syphilis of Infants and Hereditary Syphilis," in 1884. It is worthy of remark that Mr. Jonathan Hutchinson, of London, the leading authority on syphilis in Great Britain, has arrived at conclusions identical with my own in regard to the nature of the so-called hereditary syphilis. Thus in his "Pedigree of Disease," published in London, 1884, page 90, he says: "A child, then, I assert, inherits syphilis in precisely the same sense and in precisely the same manner as it may inherit small-pox. It inherits not the diathesis but the disease. The reason why the inheritance of small-pox is rare, while that of syphilis is unfortunately common, is simply that the period during which the virus is extant in the blood is very different in the two cases. The conspicuous facts then, in reference to the syphilis of infants, afford no proof that the diathesis of syphilis, any more than those of the other exanthemata is capable of transmission." Mr. Hutchinson further says: "My argument, if I have made it plain, has pointed to the conclusion that no transmission of syphilis is possible, and that the child gets either nothing at all or the germs of the disease, and that in the latter case they will, subject to the laws of idiosyncracy, develop equally in all cases."

Mr. Hutchinson does not attempt to explain the grounds on which these conclusions — so radically opposed to the usual teachings of authorities — are based. It is not, however, possible that in the face of generally accepted traditions to the contrary, these questions could be settled in such a positive way through personal, clinical observation alone. Mr. Hutchinson's teaching is the legitimate and logical sequence of the acceptance of a gradual syphilitic infection through cell contact, as heretofore claimed in this paper.

Having thus indicated the limitations of the contagious element of syphilis in the matter and mode of infection, we have now reached a point where we may, I think, proceed to the consideration of the probable or possible limit of the contagious stage of syphilis in point of time. A very general impression prevails, both in and out of the profession, that syphilis is capable of being communicated to healthy persons by a person once the subject of the disease, either by contact or by heredity, throughout the lifetime of the individual. It is a common belief that when after years of freedom from any evidence of the disease any lesion is recognized as due to a former syphilis, it is the indication of a poison still remaining in the blood of the individual, and that it may be transmitted to healthy persons by contact or by heredity. It has, however, now come to be understood practically that when the accumulations of cell material which have caused the lesions of the secondary stage of syphilis, and the enlargement of the lymphatic glands at various points have been eliminated, the disease is, as a rule, no longer contagious, and persons the subjects of syphilis who have by systematic and thorough treatment been brought to this condition, are said to be cured of syphilis. The time during which the treatment is recommended by authors to be continued, is pretty uniformly fixed at about three years. If then, the patient has been free from all signs of syphilis for one year he is pronounced cured, and he is permitted to marry.

Fournier says: "The truth is that with some very rare exceptions syphilis constitutes only a temporary bar to marriage." Bumstead and Taylor say: (Fifth Edition, page 91) "It may be stated in broad terms that no syphilitic father should procreate children until two years after infection; during which he should sedulously follow a systematic course of treatment." Keyes ("Venereal Diseases," Wood & Co., 1880) says: "After the virulence of the disease has been exhausted a man may marry and should marry." Again (page 78), "In a general way it may be safely said that a man should not marry until at least three good years lie between him and his chancre, and at least one year has elapsed since the last symptom which can be ascribed to syphilis." Hill and Cooper (London, 1881) state that "Under any circumstances the shortest period between infection and marriage should be three years. . . . Under no circumstances should a person with obvious signs of syphilitic disease marry, however long a time has elapsed since his infection, for though communication is rare when several years (four or five) have elapsed, *it may still take place after as many as ten or even more years, even when the form of disease is of the character commonly called tertiary.*"

It will thus be seen that authors are not quite harmonious in regard to the safety of marriage after syphilis, although all are agreed that no marriage should be permitted, until a year after the disappearance of any lesion which could be attributed to syphilis. All, however, are also agreed that the communication of syphilis after the third year of its existence is rare. It has been determined by careful clinical observation that the contagious element of syphilis is, as a rule, eliminated within a period varying from perhaps two to four years, and that all the manifestations of disease beyond this time, apparently due to syphilis and called tertiary lesions are not entitled to be considered strictly speaking as syphilitic. Mr. Hutchinson says of them: "What are called tertiary symptoms do not constitute a necessary stage of syphilis, and are to be regarded in the light of sequelæ." This statement is corroborated by the fact now well determined that the secretions of all such lesions are innocuous; and that neither they nor the tissues, nor the blood of patients bearing such lesions contain a contagious element.

Without the *contagium* there can be no syphilis. Ricord claims that tertiary lesions are not inocuable and cannot be transmitted by hereditary descent. Bumstead and Taylor (Fourth Edition) after reviewing this matter say: "Hence we consider the blood and the secretions in tertiary syphilis innocuous." Diday performed inoculations with the blood of persons in the tertiary stage of syphilis with a negative result.

If time permitted I think it could be satisfactorily proven to you that the tertiary lesions of syphilis are invariably due to obstructions of lymphatic spaces and channels, the result of simple pathological changes occuring during the active or contagious stage of syphilis. I will simply say that it has been determined through microscopic examination that *all* the lesions of tertiary syphilis are characterized by an accumula-

tion of so-called gummy material and that this gummy material has been found not to differ in any essential respect from normal germinal material, and that the damage associated with it may, in every case, be fully accounted for by the mechanical influence of its presence. It is to the occasional occurrence of tertiary lesions in persons who have passed through the active stage of syphilis, that a persistence of the syphilitic diathesis, with all its power of communicating syphilis for an indefinite period, even possibly through the lifetime of a patient is claimed. If, therefore, it can be absolutely proven that the active or contagious stage of syphilis does *not* last indefinitely, and that the lesions of the tertiary stage and the blood during this period are also free from the contagium, we may then hope to reach some definite limitation of the contagious stage of syphilis in all cases.

The acceptance of the degraded human germinal cell as the true contagium of syphilis and its logical sequences as determined through our present knowledge of minute physiology and pathology will lead towards, if not definitely to, such a result. But it is to competent and well authenticated clinical records that we must now look for the solution of the important question at issue.

In the recent work on "Syphilis et Mariage" M. Alfred Fournier (for the purpose of justifying his statements that syphilis is but a temporary bar to marriage previously quoted), has presented a series of eighty-seven examples occurring in his own experience. In presenting the carefully tabulated report of these cases, he says: "For my part alone I have in my hands, to speak only of written facts, eighty-seven observations relative to syphilitic subjects, undoubtedly syphilitic who, having married, have never communicated to their wives the least suspicious phenomenon; and moreover, these eighty-seven have produced among them a total of 156 absolutely healthy children."

In examining the tabulated records of these eighty-seven cases (Fournier, "Syphilis et Mariage," page 231, et seq.) I found that thirty-six out of this number of men who were thus proven to be free from any power to transmit syphilis, either by direct contact or by heredity, were subjects of late or tertiary lesions, *after marriage*, some *before* and some *after* the birth of children. These lesions comprise almost all the varieties of the sequelæ of syphilis, thus: gumma of the penis, palmar psoriasis, dry tubercular syphilide, gumma of velum palati, cerebral syphilis, papulo tubercular syphilide, costal periostitis, cerebro spinal symptoms, evidently of syphilitic origin, diplopia, passing attacks of hemiplegia, nasal syphilides, ecthyma of legs, syphilitic sarcocele, nasal ulcers, ulcerative laryngitis, papulo-squamous, palmar and plantar syphilides, sclerous and ulcerative glossitis, papulo-scaly syphilides of circinate form, tubercular ulceration, syphilide of the nose, etc.

In examining the tables of M. Fournier still farther it was found that the average time of marriage after infection in the eighty-seven cases was 5 8–10 years. That twenty-five per cent. were married within *three* years after infection, and over ten per cent. within *two* years.

In regard to the length and quality of treatment over twelve per cent. of the eighty-seven cases had treatment of less than a year's duration. Several with only a few months, one with the iodide of potash, and another with no treatment at all.

In this enormous mass of evidence, consisting of eighty-seven authentic examples, involving prolonged observation of 230 individuals adduced by an acute, thorough and competent observer, we have, what I shall claim, as absolute proof, first, of the non-contagiousness of all lesions of the tertiary stage of syphilis; second, of the possibility of the spontaneous cure of the contagious stage of syphilis (that is, without treatment) as shown in one case where there was no treatment, and in another case where only the iodide of potash was used. Third, that the limit of the contagious stage in syphilis may then, it seems to me, be certainly fixed at a point within the period of five years.

For my own part I have never seen a case of syphilis presenting an undoubted lesion of the secondary or active stage after the termination of the second year. I have seen a goodly number of cases of recurring papular syphilide, especially upon the hands and feet, occasionally upon the body, two and three years after an infection which had been thoroughly and systematically treated from the beginning, and I have always considered them as due to damage done to the lymph channels during the previous active stage of syphilis. After the third year in three such cases, marriage has been entered into with my consent, and in two, recurrences *in the identical places formerly occupied* took place nearly a year after marriage, and in both these cases the wife remained un-infected, and healthy children were reported, one now three, and the other two years old. I have seen frequent lesions of the tongue from two to a dozen years after infection, the sequel of mucous patches occurring during the active stage, which had been asserted by physicians to be mucous patches and capable of transmitting syphilis. Sometimes these would present simply as pale pearly stains or whitish patches, sometimes erosions and ulcerations and cracks again appearing as irregular spots covered with a white or grayish pellicle or scales with more or less induration. Such lesions I have never known to prove a source of syphilis to others, although coming into most intimate contact, such as between man and wife, for a series of years during which also occasional recurrences had taken place. Hence I do not hesitate to state that such forms of trouble occurring as a sequel of syphilis three years or more after infection do not contain the contagious property of syphilis and hence cannot communicate it. I have also seen numerous cases and observed them during long periods in which marriage has taken place from three to twelve or more years after a syphilitic infection of the father, and I have never yet seen a single symptom of syphilis in the wife or in the children born of such marriage. In one case reported in my class-room lessons and in my work on "Syphilis and the Genito-Uninary Diseases" five years after such a marriage, mucous tubercles appeared in the wife who, moving in good society was also apparently above reproach. The husband had been three years treated by me for undoubted syphilis previous to marriage, but he had never been free from the fear that he should sometime communicate syphilis to his wife. He accepted her syphilis as a result of an infection from him, and I was almost compelled to the same conclusion although it stultified my belief and public teaching for the previous five years. By a fortuitous train of circumstances, I was, however, enabled to obtain a confession from her, of an accidental carnal contact with an old lover, who

subsequently wrote to her inquiring after her condition and stating that while apparently well, except a little erosion on his penis, he found afterwards that the erosion was a chancre and he feared he had given syphilis to her. In the reported cases where syphilis has been claimed to have been contracted from persons whose syphilis had its initation three or more years previously, I believe that if the truth could be ascertained it would be shown that the disease was not contracted from such erosions, but always from a source less than three years from date of the infection. The overwhelming evidence as to the improbability of the communication of syphilis after the first three or four years from the date of infection as shown by the statistics of Mr. Fournier, should lead to the greatest opposition in accepting cases alleged where syphilis has been apparently acquired in contradiction of this position.

The traditions of syphilis claim that, once a man has had syphilis, he is a possible focus of contagion forever, and any evidence that a man has once had syphilis, is held as competent to prove that any syphilitic accident in his family, to the latest generation, may be reasonably credited to him. The important fact that syphilis may be and often is communicated through other sources is practically ignored. Syphilis from mediate contagion is common. It may be through the medium of a spoon, a pencil, a cane, a cigar, a kiss, the dentist's instruments. The accoucheur may acquire it through his finger. Nine cases of this sort I published some years since as occurring under my own observation, and I have seen several others since that time. Besides this, I have seen at least double that number of cases of syphilis, where no possible trace of the source of contagion could be ascertained.

A cup or any other article in common use, defiled with the secretions of a mouth, harboring a mucous patch, coming in contact with a crack, or abrasion of the lips of a healthy persons, may communicate syphilis through a resulting lesion, which shall pass away unnoticed. Any similar contact with the blood of a person in the active stage of syphilis, will communicate it. And yet, if the resulting syphilis is not distinctly traced to some one of these sources, the disease, where possible, is referred to some person who has been found to have had syphilis perhaps a quarter of a century before. It is the tradition based upon the everlasting contagious nature of the disease that the profession are wont to fall back upon to explain the mystery. Even M. Fournier is not free from the tyranny of this unproven tradition. Notwithstanding the convictions that his intelligent experience has imbued him with, that syphilis is not liable to be communicated by any person after the first three or four years from infection, and which impel him to state that *syphilis is but a temporary bar to marriage*, and which also make him say, "Yes, a hundred times yes, a man may marry after having had the pox, and the result of such a marriage, under these conditions, may be absolutely safe, medically speaking." Yet Fournier subsequently says: "We must still recognize some rare exceptions where the disease retains its contagious properties indefinitely. Such, for example," he says, "is the case of a patient whom I treated some time ago. This young man had been infected with a syphilis five years before, which one could fairly call mild, since the initial chancre was only followed by a roseola, a palmar syphilide of slight intensity, and a sore throat. He treated it, almost from the beginning, sufficiently well: several times he submitted, under my advice, to a strong mercurialization (fifteen to twenty centigrammes of proto-iodide daily). Well, in spite of this treatment, and in spite of all my efforts, the patient (who, by the way, is a smoker, a circumstance essential to note) had not ceased to be affected, during a period of five years, with lingual syphilides almost continuously. I cured him of one breaking out: one or two months later a new one attacked the tongue. Then came a new treatment, followed by a new cure: then reappearance of the malady, and so on. To be brief, I always cured him, and it always began again, to use his own expression. Now that he has completely given up tobacco (at my earnest solicitation), the eruptions become less frequent, but have not altogether ceased; and quite lately I have again seen him with syphilis coming on the back part of his tongue. Now, what would have happened if, relying on the mild nature of his disease, and satisfied as to the treatment followed, I had allowed the patient to marry, between the two outbreaks of such symptoms? What would have happened, I need not predict theoretically, because I have had a practical demonstration. This young man took as a mistress last year, a woman who till then was perfectly healthy; exempt from every venereal symptom. Some weeks later he brought her to me, affected by an indurated labial chancre, manifestly received from the lingual syphilides of the patient."

This case, and as he does not allude to any other, presumably the only one in his own experience, is presented as a typical one, to illustrate the possible persistence of contagious lesions after many years, notwithstanding the disease is of mild form, and has been systematically, persistently and efficiently treated, "almost from the beginning."

Now, is such a conclusion sufficiently warranted by this evidence, on a matter of such moment? Let us look at other causes equally possible, equally probable. The young man did not take for a mistress a woman whose virtue was above suspicion. Such a coincidence, as the contact of such a woman's lip, with some other lip, with fresher syphilitic lesions, would not be so extraordinary, as the acquirement of syphilis, from a lingual lesion, five years after infection. Such a woman would be quite in line of coming in contact with persons having active syphilis, and, either directly or by mediate contagion, might have acquired her labial chancre, even if she had not become this man's mistress, without exciting special comment.

Let me place here in contrast to this, a case taken from my own carefully recorded experience. A young man had undoubted syphilis; from the first under my own observation, characteristic initial lesion, general gland enlargement, roseola; no pronounced papular eruption; mucous patches on tongue and inner surface of cheek. After a somewhat desultory treatment, of two years, he was apparently well. Remained free from all trouble for two years; then began to have ulceration at the side of tongue, pearl color at edges; characteristic appearance of the so-called chronic mucous patch; was greatly addicted to tobacco, tongue resisted local treatment, unless accompanied by exclusion of tobacco! repeated recurrences for nearly five years; not markedly affected by specific treatment, which was tried from time to time, when at last, he married a *virtuous* girl. Since that time, already four

years have elapsed, and the wife has not had a symptom of syphilis. As a result of this marriage, there is to-day, a perfectly healthy child three years old, and yet within the last month her husband has consulted me in regard to a recurrence of the ulceration at the border of the tongue.

M. Fournier ignores entirely the possibility of accounting for the initial lesion of the lip, in the rare case he quotes, in any way, except through the chronic lesion, which his history has shown, chiefly to be dependent, for the difficulty of cure, on the use of tobacco. This one case is placed squarely, as an offset against his eighty-seven cases, some of which were also cases of ulceration of the tongue, incontestably proved to be free from the contagious element of syphilis by the immunity from infection of the eighty-seven wives and one hundred and sixty-seven children involved. It is true he brings forward a few cases, in the practice of other physicians, to prove the possible inoculability of late lesions of syphilis. But these, in the face of such statistics as he has given us, are not to be accepted, while they all open to explanation, in various reasonable ways, independently of the claim of a contagious element, persisting for years from the date of infection. When we consider the important interests at stake in a just conclusion of this matter; when we realize that thousands of individuals acquire syphilis, every year, often innocently, and that very many of these are now doomed to suffer a life-long apprehension of communicating the disease, and this too, it is claimed without reason. We cannot admit in the adjudication of the point at issue any evidence unfavorable to such claims, without the strictest scrutiny, nor accept any but the most unequivocal facts. We cannot allow even such an authority as M. Fournier to force the acceptance, without question, of a conclusion, in such direct antagonism with the mass of positive and conclusive evidence that he has given us of the non-inoculability of the late lesions of syphilis. We are, I assume, fully warranted in claiming that the explanation of the only case, which he brings up directly, to prove that the late lesions of syphilis may, in exceptional cases, be contagious, undoubtedly lies in the acquirement of syphilis from a source quite independent of the seven years old lingual lesions to which he hastily attributed it. Eliminating this case, we have then a solid mass of evidence, which on any other point, would be absolutely conclusive.

In support of this, we have also, the failure of all experimental inoculations, with the secretions of the late lesions of syphilis, which have been failures *in every instance*. We have also the knowledge of some of the various occult ways in which syphilis may be acquired, defying absolute demonstration. In the absence of an old syphilis in the husband, we have various ways of accounting for repeated abortions, and pemphigoid infants, which rest upon the diagnosis of syphilis as a cause when such syphilitic history in the male parent might have been accepted, before we knew that the semen does not contain the contagium of syphilis. The great discussion in the Academy of Medicine in Paris, a résumé of which is given by Diday, (page 72 of his work on "Infantile Syphilis") shows that the conclusion was arrived at that "Pemphigus of the fœtus, was not an immediate result of syphilis, but an indirect sequel of the exhaustion which this disease produces." Disease of the placenta caused by syphilis has been shown to result in the continuation of abortions and the production of diseased infants, independently of the continuance of any contagious element in the mother, and thus we may reasonably eliminate the contagium of syphilis, as a necessary factor in the production of such accidents.

With this presentation of some of the facts and arguments which may be brought to bear in favor of a positive limitation of the contagious stage of syphilis to three, and at farthest to four years, with or without treatment, I rest my case.

RECTAL DISEASE OF UTERINE ORIGIN.[1]

BY C. P. STRONG, M.D.

Nearly every subject in gynæcology has been so thoroughly written about and illustrative cases so multiplied that it was with surprise I noted the lack of definite and detailed information regarding the causative influence of uterine disorders in cases of rectal disease. The literature of the subject, as found in the larger text-books is but the most general statements, while in monographs it is treated more from the point of view of the rectal specialist than the gynæcologist. It being my fortune to have several patients whose symptoms were mainly or entirely rectal, I sought to find some classification of symptoms or of lesions recorded, that would aid me in determining just how far I was justified in attributing their condition to uterine disease. My search was so unproductive that I have been encouraged to contribute the results of my personal observations and a few illustrative cases with the hope of adding, although it be but little, to the general knowledge.

There are certain symptoms that suggest at once rectal examination; constipation alternating with diarrhœa, frequent and ineffectual attempts at defecation, painful defecation, hæmorrhage, muco-purulent discharges, sensations of fullness in the rectum with general reflex disturbances of the digestive tract; and when one finds, associated with these symptoms, the lesions, internal hæmorrhoids, subacute and chronic proctitis accompanied usually with fissure of anus and often with ulceration of the rectal mucous-membrane, certainly an investigation of the uterus and its adruxa is demanded. I do not intend to imply that these conditions necessarily mean uterine disease, for there is a vast number of other sources from which they may arise, but rather, that when uterine disease does cause rectal trouble, these are the symptoms, and these lesions present, and that cure will be more certain and speedy, and relapses less frequent, proportionally to the attention paid to the uterine complication. Certain conclusions, too, I formed as to the nature of the uterine disorders that would produce these lesions: first, uterine malpositions, especially retroflexion when adherent, and retroversion, prolapse associated with laxity of the vaginal walls; second, periuterine cellulitis, most markedly when retrouterine and hardening and fixing the anterior rectal wall.

There are several reasons for the disturbing effect of uterine malposition upon the rectum, but the important one is the disturbance of the veinous circulation in the lower part of the bowel, which has both a mechanical and physiological explanation. The internal hæmorrhoidal veins, valveless and thin-walled, as

[1] Read before the Obstetrical Society of Boston, December 12, 1885.

they emerge from beneath the mucous membrane through the muscular coat of the rectum, pass through openings that are readily compressed; also, this lower part of the rectum is especially rich in its nerve supply, and the mal-placed uterus, depressing the rectal wall at this spot, acts as a stimulus, producing contraction of the muscular coat of the intestine, which occludes the veins and dilates their terminal branches. So far the conditions are analogous to those occurring during normal defecation, and if now the uterus were raised all would be well, but it maintains its place and under the stimulus of its presence the contractions of the muscular wall become constant, the dilatation of the veins is permanent, and internal hæmorrhoids are produced. Passive congestion of the area drained by the veins ensues, and with this a sub-acute inflammation of the mucous membrane leading to increased secretion and loss of epithelial covering, thus adding new factors for further disturbance. Coincident with these changes the usual alterations in the uterus consequent upon its displacement, continue rendering it more and more a source of irritation to the rectum. When the uterus is in its normal position and movable, although it may press firmly against the rectal wall it stimulates no contractions, because of the deficient nerve-supply at this point of the rectum, and because its position is so constantly varying; if, however, it is fixed by adhesions a new element is introduced, the condition is then analogous to a rectal stricture, formed by retro-uterine cellulitis, an obstacle is opposed to the normal descent of faces preventing the regular and complete emptying of the rectum, irritating masses may be retained in the dilatations above and below, causing ulceration of the mucous membrane, and starting a new series of evil results.

There are two conditions that I pass over, content with merely naming them, their dependence upon uterine complications and their treatment being so obvious, hæmorrhoids during pregnancy, rectocele from a prolapsed uterus.

I have preferred not to enter too minutely into the various pathological changes that may occur in the rectum in consequence of uterine disease, because that would involve considerable theoretical discussion and necessitate a consideration of the mutual reflex disturbances, and my purpose in this paper has been only to record the results of my personal observations, therefore I pass at once to the cases I have selected as illustrative of the types of uterine disease whose symptoms are mainly rectal.

CASE I. Hæmorrhoids, internal and external, with profuse hæmorrhages and chronic proctitis. Caused by an enlarged and retroflexed uterus. Recovery without rectal treatment.

Mrs. X., widow, five years past the menopause, complexion anæmic and sallow, suggestive of malignant disease. For ten years has suffered from hæmorrhoids, which during the past two years have given her no rest night or day. Severe constipation, partly acquired as each dejection was accompanied by loss of blood, not infrequently to such an extent as to cause syncope. Protrusion of masses from the rectum at each defecation with abundant mucous discharge. Frequently confined to bed for several consecutive days. She had about exhausted the medical treatment of the rectum, having sought relief from many sources and refusing the operation that was finally urged upon her by all whom she consulted. As to the uterine symptoms, she had none, except backache, which of course could be readily explained by the condition of the rectum and her general poor health. The anus was surrounded by a fringe of hæmorrhoids, not inflamed but full of blood. Slight straining on the patient's part protruded about three quarters of an inch of the rectum turgid, streaked with blood and mucus; the numerous veins dilated to their utmost limit. The mucous membrane was thickened and here and there denuded of the epithelium, bleeding at the gentlest touch. Passing the finger up the rectum at the distance of an inch and a half to two inches it came against a firm globular mass occupying the whole calibre of the canal, suggesting at once a large rectal polypus, but noticing its apparent relation to the cervix as felt through the rectal wall, the diagnosis of retroflexion with adhesions was made and confirmed by vaginal examination. The uterus was much enlarged, three and a half inches was the internal measurement, although the catamenia had not appeared for five years. Both walls of the vagina were also lax. Owing to the tenderness of the rectum it was a matter of considerable difficulty to replace the uterus, but this was successfully accomplished by packing for two months, and then a retroflexion pessary readily retained it in its normal position. The amelioration of the symptoms when the pessary was substituted for the packing and the uterus lifted well forward was most marked and immediate. Bleeding ceased at once and has never recurred during the fifteen months she has been under my observation. Regular daily dejections, without pain, have been established. The internal hæmorrhoids have almost disappeared and the external ones form merely a fringe of hypertrophied skin. The uterus has decreased one-half inch in size and the patient's general health and strength has improved in a corresponding degree.

This case is especially interesting, because from the first visit to the last, a week ago, the only treatment has been directed to the uterus, notwithstanding all the symptoms were rectal. There has only once been any indication of a relapse. After an absence of three months, the patient returned and stated that for a few weeks past she had been troubled by the old sensation of fullness in the rectum, unaccompanied, however, by any graver symptoms. Examination showed that the uterus had bent backwards over the upper bar of the pessary and was pressing into the rectum. Replacement of the uterus and the insertion of a slightly longer pessary effectually cured this symptom.

CASE II. Subacute proctitis with fissures of the anus, dependent upon a slightly prolapsed uterus. Rectal treatment ineffectual until the uterus was replaced. Cure.

Mrs. X., aged forty, multipara, of exceptionally nervous temperament, has suffered since puberty with various uterine disorders, and has been under constant treatment for years. When she first consulted me, two years ago, there was dysmenorrhœa, leucorrhœa, inability to stand or walk, backache, and a host of kindred uterine symptoms, but during the past two years or more these had been overshadowed by rectal disturbances; constant pain in the rectum, acute suffering so intense during defecation that the act was postponed to as infrequent intervals as possible, profuse muco-purulent discharges, slight staining of the stools with blood. One of the most prominent symptoms, which she called "rectal neuralgia," was pain of severe character about the anus and lower part of

the rectum, induced by surface chilling of the body, so that even in summer she never approached an open window without protecting herself by a thick shawl. Ether was necessary for an examination, and there was found the following conditions: a slight fissure of the anus; subacute inflammation of the rectal mucous membrane, extending quite as high up as the rectum could be exposed to view, the surface streaked with lines of pus and thick glairy mucus, and studded with minute, red, granular elevations, looking not unlike grains of red pepper. The uterine condition was not encouraging. Both tubes were dilated, especially the left one, which appeared about three-quarters of an inch in diameter, and outside these tubes there was considerable inflammatory deposits. The uterus lay about an inch below its normal level, pressing back firmly into the rectum. Rectal treatment was at once begun by stretching the sphincter, cleansing the mucous membrane and applying a strong solution of nitrate of silver. For several weeks a varying treatment was employed, including absolute rest in bed, hot rectal douches and astringent applications, but beyond the improvement caused by the healing of the fissure, her symptoms were but little benefited. Then the uterus was raised and kept free from the rectum by a pessary, and coincident with this manœuvre there was steady gain. The purulent discharges ceased and the pain disappeared. An examination four months ago showed a perfectly normal appearance of both rectum and anus. There has been no relapse. The uterine condition and enlarged tubes have also improved, contrary to my expectations, under mild treatment, and except considerable dysmenorrhœa, the patient declares herself perfectly well, although it will be some time yet before I shall venture to permanently remove the support. The so-called "rectal neuralgia" is now never noticed. The rectal treatment of this case that was attended with the most benefit was the employment of suppositories of iodoform and hydrastin night and morning.

CASE III. Chronic proctitis, with anal fissure dependent upon cellulitis, extending behind the uterus and involving the anterior rectal wall, combined with prolapse of the uterus and left ovary. Improvement.

Mrs. X., thirty-six years. As with the preceding cases, the symptoms for which relief were sought were rectal. As stated by the patient, there was pain, discharge from rectum, resembling the white of eggs, or else yellow; inability to have a movement without employing both physic and enema, and often three or four enemata were required. The pain accompanying defecation is excruciating, often patient faints; and the rectum is never free from a feeling of fullness and soreness. The rectal symptoms were not very chronic, having lasted but six months, but for about a year, in consequence of a fall, patient had suffered from serious uterine troubles, for which she had received beneficial treatment. Previously to this accident she had been in good health. For the past three months, she had been in bed most of the time. Examination under ether revealed the presence of several superficial fissures in the posterior part of the anus; the rectal mucous membrane was thickened, of a dusky hue, and thickly sprinkled over the surface were minute ulcerations, varying in sizes from a pin head to a split pea. Pus and mucous abundantly present. On the anterior wall was a projection caused by the fundus of the uterus, which was firmly bound there by cellular inflammation, thus acting as a direct mechanical obstacle to the descent of the fæces. The rectal wall was so thickened and undurated, it could not be depressed to permit examination above. The uterine conditions were, a hypertrophied uterus over three inches in depth, lying low in the pelvis and rendered immovable by a mass of cellulitis, which involved as well the left ovary and the anterior rectal wall. From the sequence in time of the rectal and uterine diseases, it was quite evident that the former was dependent upon the latter; but until there was some improvement in the condition of the rectum it was hopeless to attempt any manipulations leading to re-position of the deplaced organs. Fortunately the most acute and troublesome rectal symptoms, the painful defecation and discharge of pus, improved by the dilatation of the sphincter, the use of hot rectal douche with weak solutions of nitrate of silver, and employment of the iodoform suppositories, so that very soon it was possible to treat the uterus directly. The gain was so rapid when the cellular effusion was absorbed and the uterus became movable, that rectal treatment was then entirely abandoned. At the end of five months the only reminder of the previous trouble were constipation, which was easily controlled by a laxative, and the presence of considerable mucous discharge, if the patient was long on her feet, showing that the rectum was still affected by the pressure of the prolapsed uterus and ovary.

The patient refused to wear a support, and so I have reported this case as improved, not cured, for I have no doubt that a recurrent attack of cellulitis will bring on her rectal symptoms again. It is about a year since she passed from my immediate observation, and there has been no opportunity since that time to make a local examination, but I have been informed that she is attending to her duties, and is not apparently an invalid.

CASE IV. Chronic proctitis, with deep ulcerations and fissure of the anus, dependent upon a retroflexed and adherent uterus. Rectal treatment ineffectual until supplemented by replacement of the uterus. Cure.

Mrs. X., thirty-two years, multipara. Consulted me in November, 1883. Her symptoms were both uterine and rectal, but the latter assumed the greater prominence. From the graphic and intelligent history she furnished, I make an extract of the important points. Since the establishment of her catamenia, at the age of seventeen, she suffered greatly from dysmenorrhœa, backache, and bearing-down pains; symptoms exaggerated by constantly standing, as her duties as teacher demanded. In 1871 constipation became a symptom of increasing prominence, and to this was joined hæmorrhage at each defecation. Usually she made several abortive attempts to secure a dejection before being successful, and was subject to constant pain in the rectum. For four years she was under treatment by diet and medicine, and then, passing into other hands, was examined and cured of fissure of the anus by dilatation of the sphincter. There was very great gain in the rectal symptoms after this treatment for several months, but the uterine symptoms remained unchanged, and slowly the rectum returned to its former condition. In 1879 she had an attack of peritonitis, and after convalescence from this she thus describes her condition:

"There were five or six daily attempts at defecation, the fæces were hard, dry, and in small pieces, not over an inch and a half long and shaped like the handle

of a silver dinner knife, having on one edge a streak of bright red blood and considerable amount of greenish yellow matter on the end." With these conditions unchanged the patient was married two years later, that is, in 1881. Marital life and duties exerted a most pernicious effect. She failed steadily, and when I first saw her, two years later, she was in a deplorable condition: emaciated, exhausted by pain, spending most of her time in bed, unable to walk or even stand for any length of time. She said she did not mind the backache or dysmenorrhœa, but that the trouble in the rectum was "killing her." At first I thought there must be malignant disease of the rectum to produce such depressing symptoms, but recognizing the sharply retroflexed uterus pushing into the rectal walls, and the presence of adhesions, I determined to try uterine treatment alone. A few attempts convinced me of the impracticability of accomplishing anything by this plan until there was greater tolerance of the rectum toward the necessary manipulations. Under ether the sphincter was dilated, showing several superficial and one deep fissure, and permitting the escape of a gush of blood and pus. When the sphincter was fully opened and the speculum in position, a single ulceration appeared, extending from the anus to a point about five inches up the bowel and involving the entire circumference of the rectum, except a strip of mucous membrane, varying from one-half to three-fourths of an inch in width, on its anterior aspect. This little strip of membrane was swollen and boggy from infiltration, and there were deposits of lymph on the surface from which the epithelium was very easily detached. A dark, grayish, dirty-looking coating covered the surface of the ulceration, exposing an easily bleeding granular base on its removal. Whatever the remote cause of this state of affairs might be, there was evidently but one course of treatment to pursue, and that was to promote as rapidly as possible the cicatrization of the rectum. I thoroughly curretted through the slough and granulations to a firm base and then brushed over with nitric acid, using the greatest care not to encroach upon the little remaining strip of mucous membrane. For three weeks the patient was kept absolutely recumbent in bed, and then for an equal space, allowed to move only about her room, spending most of the time upon the lounge. The medical treatment was a broth and beef-tea diet, aloin as a laxative, and enemeta of hot water, and iodoform suspended in liquid vaseline. The rectum at first would reject two ounces of hot water immediately, but at the end of six weeks would retain three pints and more for about fifteen minutes. At the end of ten weeks there was most gratifying improvement, but still the symptoms were not all gone. Blood and pus had disappeared from the dejections, there was almost no pain accompanying them, but the fæces retained their peculiar shape, and there was still the sensation of fullness in the rectum, inducing frequent attempts at defecation.

Examination showed, that the rectum was now completely cicatrized and the fissure healed. There was no change in the uterine condition. The patient was competent to attend to the rectal treatment and faithfully obeyed all my instructions, but after resuming her household duties, and being upon her feet a considerable portion of the day, she reported in July, five months subsequent to the operation, that the old rectal symptoms were returning, and she was alarmed lest she should relapse into her former state. Under its improved condition the rectum was tolerant of the course of packing that was necessary to raise the uterus, and this treatment was carried out until the adhesions were so far stretched that a pessary could be introduced to complete the cure. I abandoned the packing for the pessary sooner than is my custom, because of the irritating effect upon the rectum, and also because vaginismus made the operation of packing both tedious and painful. Immediately upon the successful replacement of the uterus, the remaining rectal symptoms disappeared and have never since returned. I saw the patient two weeks ago, and she said that she now had a regular daily evacuation of perfectly formed fæces, unaccompanied by pain or mucous discharge, that there was no abnormal sensation whatever referable to the rectum, that she never took a laxative to secure a dejection. In a word, as she stated it, "I never should know I had a rectum."

In reporting the foregoing cases, I have purposely refrained from entering upon the particulars of either the uterine or the rectal treatment, that the attention might not be drawn from the point under discussion by a confusing mass of details, and for the same reason have omitted mention of uterine complications that had no especial significance in this connection.

The cases have been selected from among a number as especially illustrative of the type of rectal diseases, that are dependent upon a uterine cause. That the cause of the rectal trouble was a direct consequence of the removal of the existing uterine lesions, not a coincidence, is shown by the fact, that, with one exception, Case III, the patients had previously received rectal treatment for years, improving but never getting thoroughly well, and always relapsing.

RECENT PROGRESS IN OTOLOGY.

BY H. L. MORSE, M.D.

DR. CHARLES H. BURNETT publishes[1] an article on "Hernial protusion of the mucous membrane of the tympanic cavity, through the membrana tympani, in some cases of chronic purulent otitis media." This affection closely resembles granulation tissue, or a polypus with a broad base, the points for a differential diagnosis and for treatment, are as follows: The hernia of the mucous membrane is sensitive to the touch, forms suddenly, does not bleed easily upon being touched, but bleeds profusely if wounded, and yields quickly to the proper treatment.

Polypi and granulations are not sensitive, bleed easily, as a rule, upon being touched, and are cauterized, or removed by means of the snare without pain. On the other hand, hernia of the mucous membrane of the tympanic cavity, is made worse by any endeavors to cauterize, or to remove it by the snare. It can be properly treated in two ways only, first either by the application of powdered boric acid, or boric acid and alum in the proportion of ten grains of the latter to one ounce of the former, or by the instillation of absolute alcohol. The discharge attending it, is usually slight, and of a thick, purulent character. There is no tendency to spontaneous bleeding from the protuding mucous membrane, though Dr. Burnett has observed a tendency to recurrence of the hernia at the menstrual epoch. It is also worthy of note that this

[1] Medical News. Vol. xlvii, No. 17.

affection of the tympanic mucous membrane has been observed only in women. In conclusion, Dr. Burnett says, "I have seen only two or three such cases, but their peculiar liability to be mistaken for polypi or polypoid growths, as well as their resentful demeanor to the treatment applicable to true polypi or granulations, has induced me to record my experience with them."

We notice an instructive article[2] by Herr Adolf Hommel, on a new method of treatment for deafness resulting from what is known as sclerosis of the tympanic cavity, or chronic dry catarrh with anchylosis of ossicles of the middle ear. Dr. Hommel gives the history of his own case, and that of one patient, and the results are so good, and the method of treatment so easy to carry out, that the article is here quoted, notwithstanding the small number of cases in which the method has been tried. In 1877, examination of Dr. Hommel's ears gave the following results.

Chronic catarrh of both middle ears. Hearing distance for the watch, left ear 20 cm., right ear 200 cm., moderate central cloudiness of the membrana tympani. A second examination in the year 1879, showed the hearing to be, left ear 15 cm., right ear 200 cm., and at a third examination in 1881, the hearing distance for the watch, had decreased to 10 cm. in the left ear, and 150 cm. in the right ear. Bone conduction on both sides was good.

This steady increase in deafness had come on, in spite of treatment by means of Politzer's air douche. At this time Dr. Hommel began to make use of the treatment to be described. At the end of one month the hearing distance had increased in the left ear to 15 cm., and in the right to 190 cm. At the end of six months to 30 cm., and 380 cm., respectively, and at the last examination given on his chart, a little more than four years after this treatment was begun, the hearing distance had increased in the left ear to 40 cm., and in the right ear to 615 cm., that is to say, his hearing for the watch had been quadrupled. As compared with the previous four years, when he was either without treatment, or was treated by means of the air douche, and during which time his hearing diminished in the left ear one-half, and in the right ear more than one-third, this result is, to say the least, a very satisfactory one.

The other case reported is that of a thirteen-year-old boy, who had previously had a perforation of the membrana tympani, and a discharge from the middle ear on the left side, and progressive deafness increasing from year to year on the right side. At the time treatment was begun, examination showed, a dry perforation of the anterior inferior quadrant of the left membrana tympani — bone conduction was good — hearing distance for the watch was 5 cm. There was marked cloudiness of the whole of the right membrana tympani, slight tinnitus, bone conduction was good, and the hearing distance for the watch in the right ear was 12 cm. After seven months' treatment the hearing distance in the left ear had improved to 160 c.m., and in the right to 340 cm. That is to say, the hearing in the left ear was thirty-two times as great as before, and in the right ear twenty-eight times as great. The cloudiness of the membrana had gradually disappeared. The method of treatment pursued by Dr. Hommel in producing these very favorable results is as follows: With the finger, press the tragus against the meatus auditorius externus so as to close the latter completely, making it an air-tight chamber filled with compressed air, which forces inward the membrana tympani and the chain of ossicles, then allow the meatus to open again; the outward rush of the compressed air, assisted by the springing back again of the membrana tympani to its usual position, will carry with it some of the air normally in the external auditory canal, and cause a partial vacuum there, and this partial vacuum will suck outward the membrana tympani and the chain of ossicles. So that each inward movement of the membrana tympani, will be followed by an outward movement of it, and of the ossicles. This is to be done rythmically about 120 times a minute, four or five times a day. Dr. Hommel found that too long and too frequent use of this manœuvre brought on pain in the ear, but that by temporarily omitting all treatment this disappeared.

The principles upon which this method depends, are not new, namely, a sort of passive motion of the chain of ossicles in the middle ear which increases their mobility, and an increased activity of the lymphatics and consequent absorption of pathological material. It is by this latter process that the disappearance of the cloudy thickening of the right membrana, in the second case reported, is explained. Alternately compressing and then partially exhausting the air in the external auditory canal, is one of the well-recognized methods of increasing the mobility of the stapes and of the other ossicles, by what is analogous to the passive motion which is used to increase the mobility of a stiff knee or elbow joint. The simplicity of the method proposed in this article for accomplishing this, makes it well worth a fair trial.

In the "Transactions of the American Otological Society," Vol. III, Part 4, occurs an article by Charles H. Burnett, M.D., on "The relation between chronic otitis media catarrhalis and chronic rhinitis," in which he says, "chronic catarrh of the middle ear, that is, otitis media catarrhalis chronica (non-suppurativa) is invariably associated with some form of chronic rhinitis. The latter is usually of the hypertrophic form, since only about four per cent. of all cases of chronic rhinitis are of the truly atrophic form." . . . "It will be found that the catarrhal processes in the Eustachian tube and middle ear proceed from those in the nares and naso-pharynx, and hence partake of their nature, or, that they occur simultaneously with them, and are relievable by treatment of the nasal disease; therefore, all cases of chronic naso-aural catarrh, that is, catarrh of the middle ear, may be divided into two classes, namely, the hypertrophic and the atrophic." Again he says, "It may have been observed that I have said nothing about the faucial and pharyngeal symptoms in chronic aural catarrh. It is because the nasal symptoms are so much more important, because in fact, the pharyngeal symptoms, in comparison with the nasal are unworthy of consideration as causative elements in aural disease." For the description of the symptoms and appearances of the membrana tympani in these cases, and for the methods employed by the author to treat the nose and naso-pharynx, the reader must be referred to the original article, as space to describe them fully cannot be given here; the following, however, are three of the four conclusions formulated by Dr. Burnett at the end of his article.

(1) "That there is a constant causal relation between chronic nasal and chronic tympanic catarrh, in

[2] Archiv. für Ohrenheilkunde. B. xxxiii, heft 1 erstes heft.

which throat and faucial diseases play only a subordinate part, and this naso-aural catarrh is found under two chief forms, namely, the hypertrophic and the atrophic."

(2) "It follows that, owing to this close connection between the nose and the middle ear, treatment of chronic catarrh of the middle ear, to be efficient must be coupled with that of the coexistent and causal rhinitis, and that treatment of the throat alone is of little avail in chronic aural diseases. Treatment of and by the way of, the external ear is of course useless." . . .

(4) "It behooves the aural surgeon, therefore, to inspect and treat the non-surgical forms of nasal catarrh as they occur in chronic catarrh of the middle ear, laying more stress on the condition of the nares than upon the fauces, so far as any causal relations between these parts and the deafness are concerned."

Dr. Burnett's article states forcibly the intimate connection between chronic rhinitis, and chronic catarrh of the Eustachian tube and tympanic cavity, and the necessity of treating the former, in order to secure a lasting improvement to the latter. Improper treatment of the nose is worse than no treatment at all, for by it fluids are often forced through the Eustachian tubes into the ears to the detriment of the latter, but proper treatment of the nose, such as Dr. Burnett has described in his article, combined with treatment of the ears, is the true way to obtain satisfactory results in these too often most unsatisfactory cases.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

FEBRUARY 8th, 1886, the President, DR. F. W. DRAPER, in the Chair.

DR. GEORGE B. SHATTUCK reported the following case of

ACUTE MILIARY TUBERCULOSIS.

B. K., twenty-one years of age, single, housework, born in Ireland, had scarlet fever last August, from which she made a good recovery. Otherwise, her health had always been good. Her father was said to have died from typhoid fever; the family history in other respects, was of a negative character. She was brought to the Boston City Hospital February 1st, in the ambulance, having been found by the police in a fainting condition in the street, when on her way to the Dispensary, where she had been under treatment for some days. She reported that her sickness began four weeks before — about January 1st — with languor, general malaise, pains in her bones, and chilly sensations. She had previously, a slight cough, which kept her awake somewhat at night. She kept on with her work for a week, and then gave it up, although she continued to expose herself to changes in temperature, to do some washing, etc. She had amenorrhœa for three months before coming to the hospital, and quite profuse epistaxis two weeks before; had been annoyed by vertigo, and had sweat considerably both by day and by night. She had lost, she thought, a good deal of flesh and strength, but was well developed and very well nourished.

February 1st, the temperature was 101.3°, pulse 120, respirations 40, the heart-sounds were feeble; the resonance over the lungs was normal, but there were very numerous coarse and fine sibilant and sonorous râles over both lungs, front and back; some dyspnœa; no cerebral or intestinal symptoms; urine negative. February 2d. Increased dyspnœa; some cyanosis; profuse perspiration; temperature, 101.2°, A. M., 103.2°, P. M.; respirations, 40, A. M., 48, P. M. February 3d. Same conditions, accompanied by increasing weakness. February 4th. About 6 A. M., after a fairly comfortable night, developed severe dyspnœa, the temperature rising to 105°, the pulse to 138, the respirations 48. Face and finger-tips markedly cyanosed; profuse sweating; perfectly conscious, and continued to take nourishment freely and easily. Number of fine râles much increased, heart-sounds weaker, physical signs otherwise unchanged. Steam was administered at noon, and her condition improved for a time, only to relapse towards evening, and she died about 9 P. M.

DR. W. W. GANNETT, who had made the autopsy, described the appearances found, and showed the specimens, the case being a typical one of acute miliary tuberculosis.

The body was that of a well-developed and remarkably well-nourished woman. In the pia of the under surface of the frontal lobes, were several tubercles. The pericardial surface of the left auricle showed the presence of many tubercles and a circumscribed tubercular pericarditis, evidently an extension from the neighboring portion of the lung. Both lungs were voluminous, of a red color, and very thickly studded throughout with gray, miliary tubercles.

The spleen, kidneys, and liver, showed similar tubercles, and in the spleen were also agglomerated, cheesy tubercles, the size of hemp seeds. The bronchial and lumbar lymph-glands were enlarged, and contained cheesy nodules. The lumbar lymph-glands were the larger, and were evidently the primary focus of infection. The thoracic duct and the abdominal veins were free.

DR. SHATTUCK said that the case suggested some points for discussion, arising from the difficulty of diagnosis. He had sought for the cause of disease in the history of the patient, but without finding it. She could have inherited the disposition from no one, so far as could be learned at the hospital. The great number of coarse and fine râles, unaccompanied by cerebral or intestinal symptoms, was suggestive of bronchitis extending into the smaller bronchi, and she had been much exposed to the weather. Such diffused and constant râles he had never met with before in acute miliary tuberculosis. He had not detected any dullness. Some slight change in resonance or elasticity might have been found by one who believed that it ought to be present; but in any such case, being bilateral, as well as exceedingly slight, it would be extremely difficult to detect. The mutual relations of pulse, temperature, and respiration, are of value in doubtful cases as a means of diagnosis, the respiration of acute miliary tuberculosis being sometimes rapid, out of proportion to the other signs mentioned. The only way, however, of reaching a certainly correct diagnosis in this case, so far as the speaker knew, would have been by an examination of the sputa for bacilli.

DR. GEORGE C. SHATTUCK said that he was reminded by the case, of one seen under his own obser-

vation at the Massachusetts General Hospital, whose symptoms were those of exhaustion and dyspepsia, with dyspnœa, but with little or no fever, or cough, and no physical signs. Death occurred in six weeks after admission, and the autopsy showed tubercles to be uniformly distributed through the lungs, and abdomen so as to effect percussion.

DR. MINOT called attention to a peculiar duskiness of integument of the whole body, which was frequently present in acute miliary tuberculosis of the lungs, probably the result of the slow asphyxia which affected the patient, and which, when present, was of considerable value in the diagnosis. Also to the fact that an eruption on the abdomen, resembling that of typhoid fever, was occasionally found, adding to the obscurity of the diagnosis, and causing the disease to be mistaken for that fever.

DR. R. H. FITZ said that diagnosis is always difficult in cases such as that reported to-night, and is to be made rather from the antecedents of the patient and the course of the disease, than from the physical signs. Without positive evidence of tuberculosis of the choroid or the discovery of bacilli in the secretions, the typhoidal course of the disease with the absence of symptoms of typhoid fever might excite suspicions of the nature of the case. The time necessary for such evidence was wanting in the present instance, and the clinical diagnosis must necessarily remain obscure.

OCULAR SYMPTOMS IN RENAL DISEASE.

DR. H. W. WILLIAMS reported a case seen by him on the day of the meeting, where a young lady, apparently in perfect health, had two weeks previously, lost the power of reading with her right eye, and now found vision slightly impaired in left eye. Her attending physician had not suspected anything more than, perhaps, the need of help by glasses, her vision continuing good at a distance. Examination proved that only the left eye was available for distant vision, having nearly normal acuteness; and the opthalmoscope disclosed a very large amount of albuminuric change in the retina about the optic disc, and the region of the macula lutea in the right eye, and similar considerable changes in the left eye. The urine was found to be loaded with albumen. When questioned, some headache, and not feeling very strong, were the only symptoms discoverable, except those above mentioned.

ACUTE ARTICULAR RHEUMATISM.

DR. JAMES AYER reported a case of acute articular rheumatism, which was of interest because the patient had lived to be eighty-seven, and this was his first attack.

DR. C. F. FOLSOM read a paper on

CASES OF EPILEPSY TREATED WITH BORAX.

Dr. Folsom said, in answer to questions, that he had selected these cases for reporting because, as they had been treated previously by accomplished men, who had, without doubt, paid attention to matters of diet, etc.; therefore, they were good cases in which to compare the results of the borax treatment with other methods. A perfectly monotonous diet is not always better than one more varied, and patients complain of it. Meat need not be absolutely excluded, although the diet must be carefully regulated. A good way is to get an elaborate bill of fare from a large hotel, and mark on that the things from among which the patient may choose. Undoubtedly, diet is an important element in treatment; and yet many observers must have been struck with the fact that certain patients may have attacks when using the greatest care in this respect, and at other times may be free from them while using no care at all, showing that with them, other factors are of greater importance.

DR. J. P. REYNOLDS said that he had supposed that monotony was not of so much importance as the avoidance of sources of irritation in diet. In the form of eclampsia that he sees most of, that of pregnant women, he thinks that sleep and proper attention to the bodily functions, as well as diet, are of great importance.

DR. FOLSOM said, in answer to a question by Dr. Lyman, that it is hard to generalize in regard to the effect of borax on the different forms of epilepsy. Some patients have *le petit mal* for years without having the *le grand mal*. In others, the facts are reversed, and in others, again, both forms occur. Bromide of potassium often diminishes the severity of the attacks of *le grand mal*, and at the same time, increases the number of attacks of *le petit mal*. One of these cases had the milder form of attack twenty times a day, and in her, its severity was diminished by the use of borax.

DR. WHITE inquired as to the constancy of the action of borax on the skin, when taken internally.

DR. FOLSOM answered that in four cases there had been disturbance. Two ladies had itching, with rapid exfoliation of the epithelium in the form of dry scales. One out-patient at the City Hospital gave up taking borax because of a distressing eruption. There was in him, an immense infiltration of the skin, resembling ivy poisoning, but without the brilliant coloring. This all disappeared, and the patient was able afterwards to take ten grains every second day without its returning.

DR. B. F. DAVENPORT asked as to the administration of borax.

DR. FOLSOM said that it is best given in cold water an hour and a half after meals. A few patients take it best in hot water. With either way there is often nausea, but this can be relieved entirely by adding spirit of chloroform, cardamon, or spirit of lavender to the dose. The only unpleasant effect is to the skin, and that is relieved by arsenic.

DR. LYMAN suggested the use of capsules. He thought there was nothing more revolting to take than the bromide, and is glad, on that account, that we have a new drug for epileptics.

DR. FOLSOM said that borax has been used for this purpose for five years at the London Hospital for Epileptics and Paralytics. This hospital has not given up the use of bromides, by any means. So far as he knows, borax was first used *here* at the Boston City Hospital. We must not expect too much from it in a disease in which the prognosis is rather unfavorable.

Some patients have distinct premonitions that an attack is approaching, which may be even visible to others. If such a patient goes to bed, takes five or six grains of calomel, and large doses of bromide and chloral, he may succeed in averting the attack. If, with such premonitions, the attacks come but seldom, there is no need for the continuous use of bromide.

Many patients have an aura for two or three minutes, long enough for them to select a place in which to lie down. Many such patients carry glass capsules, containing m. iii–v of nitrite of amyl, and by its use, some entirely avert the attack.

DR. H. W. WILLIAMS said that he had learned by experience that borax is often adulterated, and that if it is desired to have it pure, it must be bought in crystals.

LOCALIZED AMYLOID DEGENERATION.

DR. FITZ showed for Dr. W. F. Whitney an amyloid tumor resembling a lymph-gland, both in gross and microscopically, which was removed from below the lower jaw by Dr. Porter. Localized amyloid degeneration of the heart, larynx, and conjunctiva, had been reported. Amyloid degeneration of lymph-glands had also been recorded, but he did not recall a lymph-gland tumor in which this was a local process.

PARIETAL THROMBUS OF THE AORTA.

DR. GANNETT showed an unusually good specimen of parietal thrombus of the aorta, about the size of the last two joints of the little finger. It was of the pale variety, and had undergone central softening. The aorta showed a diffuse dilatation to nearly twice the usual diameter, and there were evidences of extensive chronic endaortitis. The individual was seventy-five years of age, and had been confined to bed for three months, as the result of a fracture of the femur.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

DECEMBER 12, 1885, the President, DR. A. D. SINCLAIR, in the chair.

DR. C. P. STRONG read a paper on

RECTAL DISEASE OF UTERINE ORIGIN.[1]

DR. FIFIELD said the reader's success was remarkable, as such cases are usually despaired of: the subject was known and spoken of, however, by writers on rectal surgery. Mr. Allingham has warned all who treat rectal disease to look out for uterine complications, not alone retro-version, but other conditions. Rectal disease may induce uterine disease, and *vice versa*. Inflammatory disease of the bladder is also interdependent on uterine disease. Charles Bell touched on the sympathy of mucous membranes with the rectum, although they are distant from it. So for a long time surgeons have been aware that in diseases of the bladder and urethra, one must look also to the rectum.

DR. BOARDMAN was pleased to hear the matter so fully and ably treated: he could confirm the writer's theory and submit cases illustrative of it. Affections of the bladder are often due to some disease of the uterus, and can only be treated successfully by attention to the latter organ. Simple retro-displacements of the uterus without adhesions are less liable to affect the rectum than when adherent; but a non-adherent uterus may be displaced under the utero-sacral ligaments, and thereby affect the rectum: such cases will often not bear pessaries and are therefore difficult to treat.

DR. BAKER said the paper was in accord with his own practice and experience: he wished that the reader, in a future paper, would consider the effect of loss of the perineal body in the causation of rectal disease. In the treatment of this class of cases which the reader had described, he had sometimes seen the rectal symptoms relieved by packing, strange as it would appear: this relief was due, he supposed, to the resulting improvement in the position of the uterus, and to the diminished congestion effected by the use of glycerine with which the tampons were moistened. He had been struck in some cases of fallopian or ovarian disease, and even in cases of uterine fibroid, by the reference of great pain to the rectum even when it showed no sign of disease. He asked the reader whether he had ever seen cases of proctitis resulting from anterior displacements of the uterus.

DR. STRONG replied that he had occasionally seen rectal disease coincidently with a heavy uterus in a position of anteflexion, when the cervix burrows into the rectum; but as a rule, he thought, anterior displacements will not affect the rectum. In his own experience packing the vagina aggravated, rather than relieved, the rectal symptoms: he could imagine, however, that packing would sometimes have a good effect on the rectum by giving uniform pressure. He was sorry to have been understood to say that no allusions had ever been made to the subject on which he had written: such a statement he had not intended to make; but that in looking up the matter he had found no satisfactory work on the subject. Much more has been written on the relations of the bladder and uterus, than on those of the rectum and uterus.

CAPUT SUCCEDANEUM: CEPHALHÆMATOMA.

DR. FIFIELD spoke on this subject and narrated a case in which, three days after birth, a bloody tumor formed over each parietal bone, unaccompanied by a bony ring: the blood was fluid and absorption was slow. It used to be the practice to incise these tumors, when of long standing, and he had never seen harm follow this treatment: he believed, however, that it was better to let them alone.

DR. C. D. HOMANS said that two cases of double cephalhæmatoma had been reported to the Boston Society for Medical Improvement; one by Dr. J. Homans Sr., and one by Dr. H. C. Haven, three years ago. Both cases got well without treatment. In both cases the ring of bone (so-called) was felt.

DR. BOARDMAN had seen a case of double cephalhæmatoma this year at the Boston Lying-In Hospital: the tumors were let alone and the child died.

DR. WELLINGTON had never seen the double tumor, but saw a single one a year ago, appearing the day after labor, and the child died: the child also had purpura.

DR. W. L. RICHARDSON said that he thought Dr. Fifield had two different conditions confused with each other. The term caput succedaneum was a name applied to the swelling often found in that portion of the presenting part which had escaped the pressure surrounding it. It was due to an obstruction of the venous circulation and was only a venous hyperæmia which in extreme cases might pass into an œdema or even extravasation. The term cephalhæmatoma is only applied to extravasation of blood between the pericranium and cranium. While the caput succedaneum, when present, is always seen at the time of birth, the cephalhæmatoma does not appear until twelve to twenty-four or even forty-eight hours afterwards, the blood being very gradually poured out after the delivery of the head allows of its escape from the minute vessels, which have been torn as the pericranium was separated from the cranium.

[1] See page 151.

The elevated ridge which encircles this form of tumor is at first the edge of the clot; but later, as the process of repair goes on, an inflammatory fibrinous exudation takes place and the circle appears more sharply defined and simulates a bony ridge. He had seen not a few cases of this disease among the three thousand cases at the Boston Lying-in Hospital. Many years ago he opened one and the result was an alarming hæmorrhage and the production of an abscess which refused to heal, and the baby died. Since then he had left them alone and they gradually disappeared within from four to six weeks.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING, WEDNESDAY, FEBRUARY 3.

A STATED meeting of the Councillors was held at the Medical Library, Boston, on Wednesday, 3d inst.

The meeting was called to order at eleven A.M., by the President, Dr. C. D. HOMANS. Eighty Councillors indicated their presence by signing the roll.

APPOINTMENT OF DELEGATES AND COMMITTEES.

On nomination by the Chair, the following delegates to other State Medical Societies were appointed:—

Maine: Drs. R. Amory, E. G. Cutler, of Boston.

New Hampshire: Drs. J. A. Douglass, of Amesbury; O. Warren, of West Newbury.

Rhode Island: Drs. W. Ingalls, of Boston; G. S. Eddy, of Fall River.

Connecticut: Drs. F. H. Hooper, of New Bedford; G. S. Stebbins, of Springfield.

New Jersey: Drs. F. H. Brown, of Boston; J. Seaverns, of Roxbury.

Committees were appointed:—

To Audit the Treasurer's Accounts: Drs. I. H. Hazleton, A. L. Mason.

To Examine the By-Laws of District Societies: Drs. S. D. Presbrey, J. C. White, F. W. Chapin.

AMENDMENTS TO RULES AND ORDERS.

In accordance with notice given at the last meeting, Dr. Draper offered the following which was adopted:

Voted: To amend the Rules and Orders of the Councillors, as follows:—

Paragraph 4 of Section 5, by omitting the words "obtaining . . . at the annual meeting, and also pointing out some mode in which Fellows who do not attend the meeting may obtain them;" and after the word "dinner" inserting the words "and the distribution of," so that the section shall read:

5. The Recording Secretary shall issue, and send by mail to every Fellow, one month before each annual meeting, a circular, which shall contain —

A notification of the time and place of the annual meeting of the Fellows; —

A similar notification of the stated meetings of the Councillors for the whole year, and of the stated meetings of the Board of Censors for the Suffolk District; —

All necessary information concerning the payment of assessments, admission to the annual dinner, and the distribution of the Society's publications; —

The conditions of admission to the Society, and all necessary information concerning the steps to be taken by those desirous of it.

Section 7, by striking out the word "Resignations" in the third line and substituting the word "Finances" by inserting the word "and" before the words "a Committee on Ethics and Discipline;" and by omitting all the words after "Discipline" in the fifth line; so that the section shall read:

7. At the annual meeting of the Councillors, the following Standing Committees shall be appointed: viz., a Committee on Publications, a Committee on Membership and Finances, a Committee of Arrangements for the Anniversary, and a Committee on Ethics and Discipline.

Section 8, by striking out the words "a Committee to examine the library and cabinet; also" in the third and fourth lines; and the words "all of" in the sixth line; so that the section shall read:

8. At the third stated meeting of the Councillors, there shall be chosen a Committee to examine the Treasurer's accounts, on the week preceding the annual meeting, and a Committee to examine the By-Laws of the District Societies, to see whether they conform to the Laws of the State and of the State Society; which Committees shall make their reports to the Councillors at their annual meeting.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

EIGHTIETH Annual Meeting. Held at Albany, February 2, 3, and 4, 1886.

FIRST DAY. — MORNING SESSION. — ADDRESS BY THE PRESIDENT.

The meeting was held in the Common Council Chamber. After prayer by the Rev. W. D. Nicholas, the President, DR. ALBERT VANDER VEER, of Albany, made an address of welcome, in which he suggested that every alternate year the meetings of the Society should be held in some other part of the State than Albany, in order to stimulate local interest, and stated that he favored the idea of semi-annual meetings. He also remarked upon the unfavorable character of the time for holding the meetings at present (the early part of February), on account of its being a season when other organizations were centering temporarily in the capital city; and in the latter part of his address criticized the action of the American Medical Association, in refusing recognition to those who adhered to the code of ethics of the State of New York.

COMMITTEES APPOINTED.

The following committees were appointed: —

Credentials, — Dr. S. H. Freeman, Albany, Chairman.

Business, — Dr. W. W. Potter, Buffalo, Chairman.

President's Address,—Dr. F. R. Sturgis, New York, Chairman.

Invitations, — Dr. W. C. Wey, Elmira, Chairman.

THE COMMITTEE ON LEGISLATION,

Dr. Daniel Lewis, Chairman, reported a bill pending in the Senate and Assembly to establish a State board of medical examiners. Also that bills had been passed empowering the State Medical Society to regulate and control its own membership; permitting medical societies to hold property to an amount not exceeding $100,000, and providing that no member of a medical society should be assessed more than five dollars per annum.

PAPERS READ.

The following papers were read and discussed: "The Curative Potency of Prolonged Sleep," Dr. J. Leonard Corning, New York; "History of a Case of Abscess of the Kidney," C. L. Styles, Oswego; "Abscess of the Kidney," W. S. Ely, Rochester; "Report

of a Case of Empyema," Dr. B. F. Sherman, Ogdensburgh; "The Treatment of Aural Polypi by the Injection of Carbolic Acid," Dr. Herman Bendell, Albany; "Results of the Operation for Convergent Squint," Dr. D. B. St. John Roosa, New York; "Spontaneous Expulsion of a Large Calculus in the Case of a Female aged Sixty-Eight Years," Dr. Harvey Jewett, Canandaigua; and "Vesical Calculi in Female Children, with Cases," Dr. N. A. Powell, Edgar, Ontario.

AFTERNOON SESSION. — DISTINGUISHED VISITORS.

The report of the Committee of Arrangements, DR. S. B. WARD, Chairman, was read, recommending that a large number of physicians from various parts of the State be invited to attend during the meeting, after which the following visitors were introduced and made brief responses: Drs. Wm. Gardner and James Stewart, professors respectively of gynæcology and materia medica in McGill College, Canada, and Dr. T. J. Allen, of Montreal. The

COMMITTEE ON PRIZE ESSAY,

DR. W. W. POTTER, Chairman, reported that only one essay had been submitted, and that in the opinion of the committee this does not give evidence of sufficient original research to entitle it to a prize.

PAPERS READ.

The following papers were read and discussed: "Rheumatic Affections of the Joints," Dr. A. Hadden, of New York; "A Case of Tumor of the Maxillary Antrum and Orbit," Dr. T. R. Pooley, New York; "Infant Feeding," Dr. E. F. Brush, Mount Vernon; "Peritonitis of Infants and Children," Dr. A. Jacobi, New York; "General Arterio-Capillary Fibrosis: Its Relations to Cardiac and Renal Disease," Dr. Alfred L. Loomis, New York; "Ulcerative Endocarditis, Dr. H. R. Hopkins, Buffalo; "The Early Management of Cases of Mental Depression," Dr. Willis E. Ford, Utica; and "Hints on the Treatment of Diphtheria," Dr. J. M. Bigelow, Albany.

EVENING SESSION. — PAPERS READ.

The first paper of the evening was one contributed by Lawson Tait, F. R. C. S., on "Methods of Diagnosis," which was read by Dr. S. B. Ward, of Albany. It was followed by one on "Diseases of the Fallopian Tubes, with Reports of Cases and Characteristic Specimens," by Dr. W. Gill Wylie, New York; after which Tait's operation was discussed by Drs. P. F. Mundé, New York, Wm. Hailes, Albany, W. B. Chase, Brooklyn, W. G. Wylie, New York, and the President. Dr. P. R. Furbeck, of Gloversville, then read a paper on "The Establishment of a State Board of Medical Examiners," which was referred to the Committee on Legislation.

SECOND DAY. — MORNING SESSION. — PAPERS READ.

"Case of Abscess Illustrating the Importance of Drainage," by J. W. Whitbeck, of Rochester; "Lessons in the Management of Club-Foot," by Dr. V. P. Gibney, of New York; "Ozæna," by Dr. John O. Roe, of Rochester; "Medical Testimony and the Hypothetical Question," by Dr. Wm. C. Wey, of Elmira; "Bacteria: Identification and Classification of Species," by Dr. Wm. Hailes, Jr., of Albany; "Acute Nephritis, especially as following Diphtheria," by Dr. A. R. Simmons, of Utica; "Removal of Piece of Iron from Interior of Eye," by Dr. W. F. Mittendorf, of New York; "A New Method of Operating upon Abscesses in the Soft Parts," by Dr. M. J. Roberts, of New York; "The Radical Treatment of Hydrocele and Varicocele," by Dr. E. L. Keyes, of New York; "Fatty Tumors of the Knee-Joint," by Dr. R. F. Weir, of New York; "Excision of the Knee-Joint, with Cases," by Dr. A. M. Phelps, of Chateaugay; and "Burns considered as Wounds and Treated Antiseptically," by Dr. R. T. Morris, of New York.

AFTERNOON SESSION. — REPORT OF COMMITTEE ON PRESIDENT'S ADDRESS.

The Committee on President's address reported that they favored the adoption of an amendment to the by-laws by which all delegates of three years' standing should be admitted to permanent membership on the vote of the society, provided that in case of objection to any name the matter should be referred to the committee on ethics for decision. They did not recommend any increase in the number of delegates or change in the time or place of meeting. They strongly urged the Committee on Legislation to use every legitimate means to ensure the passage by the Legislature of a bill substantially the same as that recommended by the Society at its last session, providing for a State board of medical examiners. They also recommend the appointment of a permanent business committee by the president-elect at as early a period as possible. The report was adopted.

A resolution was offered by Dr. C. H. Porter that a special committee of three should be appointed by the President to report at the next annual meeting in regard to the advisability of making any change in the number and length of term of delegates from county societies.

PAPERS READ.

"The Prognosis and Treatment of True Lateral Curvature of the Spine," by Dr. Newton M. Shaffer, of New York; "The Relation of the State Board of Health to Local Boards," by Dr. Maurice Perkins, of Schenectady; "On the Limitation of the Contagious Period of Syphilis, in Relation to Marriage,[1] etc.," by Dr. F. N. Otis, of New York; "Non-Venereal Syphilis," by Dr. L. D. Bulkley, of New York; "The Treatment of Tertiary Syphilis of the Nose, Mouth and Throat," by Dr. D. H. Goodwillie; "Pin Operation for Deviated Septum," by Dr. W. C. Phillips; "Tubercular Ulceration of the Larynx," by Dr. F. W. Hinkel, of Buffalo; "The Hygiene of the Ear: Based upon the Record of More than 2,800 Cases," by Dr. C. R. Agnew, of New York; "Some Observations on the Treatment of Uterine Displacements in General Practice," by Dr. L. E. Felton, of Potsdam; and "Croupous Tonsillitis," by Dr. L. E. Holt, of New York.

SECOND DAY. — EVENING SESSION. — ANNIVERSARY ADDRESS.

The President, DR. VANDER VEER, delivered the anniversary address in the Assembly Chamber at the capitol; taking for his subject, "The Water Supply of Cities and Villages." In speaking of the supply derived from wells, he said he was impressed with the belief that in the system of driven wells put down by the gang method we had embodied the principle of natural filtration, and that wherever the ground-water

[1] See p. 147 of this Journal.

was of good quality, sufficient quantity and proper depth, and was free from sources of contamination, it furnished by far the safest water short of what might be considered nature's purest supply, spring water.

As the water obtained by this system comes from depths of forty to one hundred feet below the surface, it is very pure, and the supply is steady throughout the year. By other systems the supply is taken from the surface water, and its quality is often impaired by local impurities, while the quantity in different seasons varies with the rain-fall. In this system the water is taken from natural recesses, reservoirs or undercurrents, and there is no exposure to vegetable or animal growths from sunheat and changes in temperature. These wells may be located along ponds and running streams, and if the water be not below their level, it is almost positive proof that the supply is from the rain-fall, springs and natural drainage area of these furnishing wells. The water in these collecting driven wells is naturally found quite free from organic matter, but must be examined carefully as to mineral substances. It is a well know fact that they often derive their supply from currents of water feeding running streams or lakes.

Dr. Vander Veer then took up the method of conveying water to cities from distant points by means of aqueducts, as in the days of the Roman Empire. The great cost of this system stood in the way of its use at the present time; but he said he would venture to predict that it would not be many years before this subject of water supply would be handled by capital and be made to pay a good dividend, and that every city and village in the State would be furnished with a full, wholesome supply of water at a reasonable price.

It was necessary to study the sources and kinds of water. There was scarcely a town in the State without some manufacturing interest to be taken into account. It was easy to talk about having one supply of indifferent water for manufacturing purposes, to control fires, etc., and another for domestic use, but the question of expense and other points occurred; often making such a scheme so intricate as to become altogether impracticable. This one broad principle was safe to act upon, that waters of excessive hardness might, in the human economy, do harm by causing or developing urinary and other diseases, while for domestic and manufacturing purposes they were often exceedingly embarrassing and expensive.

Having dwelt for some time upon the relative properties and effects of hard and soft water, he said that beyond a doubt, spring-water, as procured from deep springs, or as fed to our mountain lakes, is not only the most palatable, but the most wholesome of waters. Next, we may rely upon artesian or driven wells, keeping ever in mind the danger of sewage contamination. Large rivers may be made use of, or smaller streams fed by springs and surface water; but contamination must be guarded against with the greatest care. River water that has a long distance to run may purify itself from sewage and other forms of pollution; but it, together with water from shallow wells, must be looked upon as dangerous, though it may be pleasant to the taste and sight. The dangers of wells, cisterns, and other sources of supply becoming contaminated was adverted to and Dr. Vander Veer traced the history of various epidemics caused by polluted water; dwelling particularly on that at Plymouth, Pa., last year.

In conclusion, he said that America was fortunate in the number of springs of pure water which she possessed, and, from their cheapness, these waters were finding their way into many households for drinking and domestic purposes. Much as we might deplore it, it was a fact that a large proportion of the waters supplied by public works at the present time, required filtration. The water needed for domestic uses, therefore, should be secured, first, by gravity and from mountain streams, lakes, or springs; next, if this were not possible, by the gang syphon driven wells, provided the surroundings were safe and proper in every respect; next by a system of storage, but so arranging the reservoir that proper aëration could be employed; and, lastly, if necessity compelled, and it had to be taken from sources known to be polluted, then a thorough system of filtration should be employed and the water be as completely oxygenated as possible before distribution.

At the conclusion of the President's address,

THE ANNUAL BANQUET

was held at the Delavan House, Dr. S. B. Ward acting as toast-master.

THIRD DAY. — THURSDAY, FEBRUARY 4th. — PAPERS PRESENTED.

Several reports of committees were made; after which Dr. D. B. Simmons, of Poughkeepsie, read a paper on "Leprosy in Japan"; Dr. J. H. Bailey read one on "Hemorrhoids in Pregnancy"; Dr. W. H. Thompson, of New York, one on "The Prevention of Hemiplegia," and Dr. F. C. Curtis, of Albany, one on "Ringworm of the Scalp in Asylums and in Private Practise." The following papers were also presented; some of them being read by title: "Abscess of the Liver," by B. C. Senton, of Whitehall; "Early Ovariotomy" by Dr. T. H. Squire, of Elmira; "Cremation," by Dr. Charles Cary, of Buffalo; "Hæmorrhage after Removal of the Cervix Uterl, with the Galvano-Cautery Wire," by Dr. J. P. Boyd, of Albany; "Migraine," by Dr. F. S. Crego, of Buffalo; "A General System of Districting the State Asylums for the Accommodation of the Acute and Chronic Insane," by Dr. F. Peterson, of Poughkeepsie; "The Emission of Semen as a Means of Diagnosis of Death by Hanging," by Dr. F. N. Hamlin, of Auburn; "The Benefits Arising from Laws Regulating Pharmacy," by Dr. A. B. Huested, of Albany; "The Bacillus Ethicus Medicinalis," by Dr. S. S. Wallian, of New York; "Well-water in its Relation to Microspores," by Dr. F. E. Martindale; "The Free Dispensary System," by Dr. J. W. Howe, of New York; and "The Treatment of Epilepsy," by Dr. C. L. Dana, of New York.

ELECTION OF OFFICERS.

The committee on nomination reported the names of the following gentlemen, who were duly elected:—

President, Dr. Wm. S. Ely, of Rochester.

Vice-president, Dr. Solomon Van Etten, of Port Jervis.

Secretary, Dr. Wm. Manlius Smith, of Syracuse.

Treasurer, Dr. Chas. H. Porter, of Albany.

Honorary Members, Lawson Tait, F.R.C.S., of Birmingham, England; Drs. E. N. Brush and J. G. Richardson, of Philadelphia; Dr. T. Henson, of Copenhagen.

Medical and Surgical Journal.

THURSDAY, FEBRUARY 18, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE REPORT OF THE COMMITTEE OF THE AMERICAN PUBLIC HEALTH ASSOCIATION ON DISINFECTION AND DISINFECTANTS.

AT its annual meeting at St. Louis in 1884, the American Public Health Association appointed a committee, of which Dr. George M. Sternberg was chairman, to investigate and report upon the subject of Disinfection and Disinfectants. Unofficial preliminary reports of their work as it progressed have from time been given to the public, and a "plain, practical paper" for "popular use and distribution" had already been furnished at the request, last March, of the Sanitary Council of the Mississippi Valley, before the appearance two or three months since of the full and final official report.

The subject is one of such importance, and so much needing careful scientific illumination that any serious contribution tending to differentiate more exactly knowledge and ignorance in regard to it is deserving of hearty welcome. At the same time a report emanating from a committee composed of such well known sanitarians as is this, and endorsed by such a body as the American Public Health Association is liable to be widely circulated and the conclusions to be somewhat readily accepted and applied.

Under these circumstances some examination and criticism of the methods by which the conclusions are reached, and upon which the recommendations made are based, seem fairly indicated.

From a biological point of view, the greater part of the work done and all of the results reached are based upon the activity of certain reagents in the destruction of bacterial vitality; the method by which this activity is determined should therefore be most carefully observed and as carefully selected for its ease and precision. In the first place, the method selected by the observers in this instance does not recommend itself for the reason that the culture-flasks employed are difficult of preparation, are clumsy to handle, and have absolutely no advantages in the line of safety against external contamination over the ordinary test-tube plugged with cotton-wool, each being used by skilful manipulators.

Secondly, the method of exposing a given quantity of broken-down beef-tea with a given amount of the "germicide" under trial in unsterilized open vessels, and then transferring a portion of this material to a sterilized culture-medium in a closed vessel does not seem to us to be as precise a method as that of Koch, Miquel, Passet and others, where the germicide is introduced into a bacteria-containing medium in the first place, this material being kept in sterilized and closed vessels all the time.

Thirdly, the use of fluids and fluid culture-media is very strongly advocated by the authors of this report, but if they had felt it worth while to follow the methods most generally in use in this sort of work, by which action their results could be much more easily and definitely compared with those already obtained, very much less would have been said of such and such effects upon "the micrococcus of pus," or "the micrococcus of a vaccine vesicle." The use of solid culture-media would have shown the observers, and through them the readers, what micrococcus of pus they had under observation, whether it was the staphylococcus aureus, or albus, or possibly the streptococcus pyogenis or micrococcus tennis. This point we have now no means of knowing, and yet it is of importance for, until it is *proved* to be the case, we have no right to assume that germicides act in the same way on all of the group of bacteria which seem to be concerned in the pus-forming processes in man.

Another point in the report which is certainly open to objection, is the distinction made — more particularly in the conclusions drawn from the work done "and collated" — between agents to be employed against spore and non-spore-containing material. Such distinctions are very necessary in all experimental work in this line, and in laboratory work, they must unquestionably be very carefully determined. It verges upon the absurd, however, when they are thus made in the "conclusions" of a pamphlet like the one under consideration, which is to be the guide and familiar friend of our Boards of Health, and their deputies and inspectors.

Koch, in his great work upon disinfection, states distinctly, and with perfect truth, that in the present state of our bacteriological knowledge, it is impossible to say what are and what are not spore-producing organisms, and that, therefore, at least for the present, our reliance for general and practical use must be placed upon those disinfectants of known spore-destroying power. Since this statement was made the general knowledge of bacteria has made very great strides in advance, but nothing, with which we are acquainted, gives any more authority than then existed for contradicting the statement. Before we can say that a certain material does or does not contain spores, the kind of bacterium concerned must be determined; then this bacterium must be so well studied that at least the great probability of its not producing spores may be established; and finally, every health inspector, into whose province it comes

to say whether a spore-destroying or non-spore-destroying germicide is to be used, must have so thorough a training in bacteriology that he will not attempt to differentiate species by estimated weight and will, at least, know a spore from a micrococcus, and this latter from a piece of dirt. These results have not yet been attained, and therefore, it seems to be an entirely unnecessary complication, as well as a probable source of very great confusion, that the report should make this distinction in just the way it has been made.

Inasmuch as the specific bacteria of the acute exanthematous diseases, and even of typhoid fever or yellow fever, are as yet merely myths, or at best, only very dimly understood, there is no justification, as the report seems to imply there is, for taking it for granted that the organisms of these diseases do not produce spores, and there is, therefore, no sufficient ground for recommending the use of a non-spore-destroying germicide.

The wisdom of introducing the chapter upon commercial disinfectants is questionable. An instance of the complications to which it may give rise is shown upon page seventeen of the report, and this is probably not a solitary instance. Such investigations can only turn out to the advantage or disadvantage of certain manufacturers; the public, so far as they care about the matter at all, will employ the reagents recommended by the committee in their conclusions, and will have nothing to do with proprietary compounds *unless* they are advertised as being approved by some such authority as this. That great part of the public which does not care, and which prefers the cheapest or prettiest preparation, will certainly not go to any scientific authority for a recommendation or condemnation of what it proposes to use.

In the preface to the report (p. xii.) it is stated that "it would be desirable to test each disinfecting agent upon a variety of pathogenic organisms," and that this is "a task which should follow the more general study which we have made." The reverse of this is true, of course. A thoroughly scientific basis upon which measures for disinfection may be founded can only be reached after the investigation of each pathogenic organism has been made. This being done, then, and then only, will it be possible to say that the most effective germicidal agents are known. In order to reach such a result, however, the knowledge of pathogenic bacteria must be widely extended, and many of the diseases now seemingly taken for granted as being due to bacterial activity must be proved to be such, and not so classed by guess-work.

Biologically, therefore, it can only be said of this report that it furnishes merely a preliminary to something which must be very much wider in scope and more thorough in execution, before the conclusions advanced can be accepted as true. In other words, the work done can be considered as merely introductory and the results cannot be accepted as final — the more so as in the few cases where comparison between this work and that of Koch, Miquel, and others is possible, there are discrepancies in results which need explanation, and the reasons for which might be more clearly determined if the same methods of observation had been employed in all cases.

There might easily have been a little more distinct acknowledgment of the part played by the work of other observers in furnishing the grounds for the "conclusions" of the report than anywhere appears.

From a chemical point of view, the report of the Committee embodies the results of numerous investigations relating to the practical application of such disinfectants as have been found efficient, their cost, chemical relations, effects upon furniture or fabrics and their possible poisonous effects.

Experiments made with the proprietary disinfectants show that a large number of these are not to be depended upon for disinfectant purposes, though nearly all are perhaps more or less useful as antiseptics or deodorizers. The obvious conclusion to be drawn from these experiments is that it is much safer to employ as a disinfectant some agent, such as corrosive sublimate or a hypochlorite, the nature and strength of which is known, than to make use of preparations the composition of which is unknown and very likely variable.

The results of analyses made to determine the value of calcium hypochlorite (chloride of lime) and Labarraque's solution of sodium hypochlorite as disinfectants are interesting, since, in accordance with our present ideas, these substances are chemically among the most efficient agents at our disposal for this purpose, when of sufficient strength; their value depending upon the amount of available chlorine they contain. Preparations of sodium hypochlorite, bought in the open market were found to vary greatly in the amount of available chlorine; two samples containing less than one per cent. These variations are not necessarily due to any fault in manufacture, but rather to a gradual decomposition upon keeping. The figures given show the necessity of always determining the amount of available chlorine in these substances, before making use of them for disinfecting purposes. The sodium salt was found to be more stable when prepared by passing chlorine gas into a solution of caustic soda than when prepared according to the U. S. P. The strength of the preparation of chloride of lime was found to be satisfactory as a rule. This substance should contain from twenty to thirty-five per cent. of available chlorine.

A number of interesting experiments are described in connection with the investigations of sulphur dioxide. One of the most important of these, from a practical point of view, refers to the action of this agent upon fabrics. The strength of the fibre was impaired, while as to color only five of one hundred and sixteen samples were affected.

Most of the investigations to which we have briefly referred, together with some others relative to the action of the mineral acids and corrosive sublimate on metals are essentially repetitions of investigations pre-

viously made by others, and do not really teach us much that is new. They are practically important, however, and the committee is justified in directing the attention of health officers and the public to them.

Experiments made with reference to the danger of the passage of mercuric chloride (corrosive sublimate) from cesspools and vaults through the soil into wells, are unsatisfactory and hardly justify the conclusion reached, that the fear of poisoning the water is groundless. As corrosive sublimate promises, for a time at least, to be the fashionable disinfectant this question becomes a very important one, and we think is worthy of further investigation.

We have not hesitated to criticise this report where criticism seemed called for in the interest of the advancement of scientific hygiene and especially of applied bacteriology. But, on the other hand, we desire to express a genuine appreciation of the zeal and activity displayed by the committee in discharging its difficult duties.

VENUS BEFRIENDS ÆSCULAPIUS.

To the medical man of serious tastes, who never, in whatever circumstances of frivolity he may find himself, forgets that he belongs to the gravest of professions, and who lets slip no opportunity of perfecting himself in the principles of his art, the prevailing mode in ladies' evening toilettes offers great possibilities.

Dragged, perhaps, unwillingly from his sterner duties by the demands of social life, his time is yet not thrown away. Should surgery be his delight, he finds abundant facilities in the drawing-room or at the opera, for viewing and reviewing topographical anatomy. The triangles of the neck are often most freely demonstrated by the very class of subjects in whom the anatomical landmarks are most clearly visible. There is more difficulty in studying the axillary space in its completeness, though its anterior and posterior boundaries, the pectoralis major and the latissimus dorsi, can usually be well made out. The advance of fashion has, unfortunately, not as yet brought under observation the other regions of great anatomo-topographical interest. While mechanically paying out his share of the small coin of social converse, the surgeon is really making the incisions for ligature of the subclavian, the brachial, and the innominate; he is considering how the appearances would be changed in case of a fracture of the coracoid process, or a dislocation of the humeral head, or of the sternal end of the clavicle. Perhaps he is planning out an operation for the ablation of the mammary gland. Who knows?

If chest diseases are his specialty, he lays out the boundaries of the pulmonary lobes, wonders if the cardiac dullness extends further to the left than the line which his practised eye describes as the normal boundary, and upon the lady who stands in front of him, determines the proper point to enter a needle for thoracentesis. These opportunities are not to be lightly overlooked by any.

MEDICAL NOTES.

— The hospital physicians and surgeons of Paris, to the number of one hundred and six, have signed a petition addressed to the Minister of the Interior, praying that the *religieuses* in the hospitals to which they are attached may be retained. In the present temper of the French people, it is thought that this petition will not be granted.

BOSTON.

— The late Henry P. Kidder left among his public bequests, reversionary legacies of $10,000 each to Harvard College and the Massachusetts General Hospital and $3,000 to the Children's Mission to the Children of the Destitute. Mr. Kidder was a State trustee of the Massachusetts Hospital.

— Mr. Nathaniel Thayer has been elected by the corporation a trustee of the Massachusetts General Hospital. Mr. David P. Kimball has also been appointed by the Governor a trustee on behalf of the State, to succeed the late Henry P. Kidder.

— In declining an invitation to dine at the Hotel Brunswick with the New York Odontological Society last week, Dr. Oliver Wendell Holmes wrote, "I often think of the forlorn condition of some of the great personages of history in the days when there were no dentists, or none who would be recognized as such by the dental artists of to-day. Think of poor King David, a worn-out man at seventy, probably without teeth, and certainly without spectacles. Think of poor George Washington, his teeth always ready to drop like a portcullis, and cut a sentence in two. See him in Stuart's admirable portrait, his thoughts evidently divided between the cares of empire and the maintenance of the *status quo* of his terrific dental arrangements. Think of Walter Savage Landor's melancholy complaint that he did not mind losing his intellectual faculties, but the loss of his teeth he felt to be a very great calamity. I will venture to propose, then, the dental profession and their association as its worthy representative: It has established and prolonged the reign of beauty; it has added to the charms of social intercourse and lent perfection to the accents of eloquence; it has taken from old age its most unwelcome feature and has lengthened enjoyable human life far beyond the limit of years when the toothless and purblind patriarch might well exclaim, 'I have no pleasure in them.'"

NEW YORK.

—A second physician has fallen a victim to typhus fever in the discharge of duty in connection with the epidemic of that disease in the penitentiary at Albany. Dr. James A. McCoughlin, one of the volunteer staff of physicians during the epidemic, died February 12th, after an illness of about a fortnight. There are now only three cases of typhus among the prisoners in the penitentiary.

— Dr. John S. Billings, of Washington, delivered the first of a popular course of lectures at Columbia College, February 8th. His subject was "The Uses

and Dangers of Micro-organisms," and in the course of it, he expressed his regret that the study of microbes tended almost entirely to the investigation of the mischief which they wrought. "But they do more than that," he said, "they are everywhere, and their function is that of the unbuilders. We live at the bottom of a great gaseous ocean, the atmosphere, of which nitrogen gas is the chief component. This is a 'mugwump' sort of a gas, which is generally neutral, but on occasions, makes serious explosions. This gas is absorbed by plants in building up their structure, but when a plant dies or a tree falls, these organisms unbuild the structures and make nitrates, which ferment wine and fruit, purify rivers, and prevent diseases." Having mentioned that the study of such organisms had taught men to ship and carry fresh meats with safety, and, in certain instances, to protect individuals against diseases, one attack of which prevented others, he concluded with an appeal for more laboratories and more investigators in this department of sanitary science.

— Dr Alfred C. Post, the oldest and one of the most distinguished surgeons of New York, died of cystitis, after a few days illness, on the 7th of February in the eighty-first year of his age. He was the son of Joel Post, a prominent merchant, who occupied as his country-seat the property on the Hudson known as Claremont, now forming a part of the Riverside Park, and embracing the site of Gen. Grant's tomb. He was graduated from the academical department of Columbia College in 1822, and from the College of Physicians and Surgeons in 1827. He then went to Europe to further prosecute his medical studies, and after two years spent in Edinburgh, Paris, Berlin and other centres, began the active practice of his profession in his native city, and industriously continued it until the week before his death, a period of nearly fifty-seven years. From the first, he devoted special attention to surgery, in which department of medicine he quickly acquired a distinguished reputation, and as early as 1836 was appointed one of the surgeons to the New York Hospital. He was one of the founders of the medical department of the University of the City of New York, and at the time of his death was President of the Medical Faculty and Professor emeritus of Clinical Surgery in that institution. He was at one time President of the New York Academy of Medicine, whose meetings he attended with great regularity until his last illness, and also a member and officer of many other medical societies. Dr. Post was always noted for his devoted piety, and gave largely of his means and time to various charitable and religious associations with which he was connected. One of his sons is a practising physician in New York, and another, who is connected with the Presbyterian Mission at Beirut, Syria, has also won distinction as a surgeon. The funeral services, which was held at the Presbyterian Church of the Covenant, where Dr. Post was an elder, were attended by a very large number of the profession.

— At a meeting of the Clinical Society of the New York Post-graduate School and Hospital, held January 25th, "Hydrophobia and Its Prevention," was the subject of discussion. After a few introductory remarks by its President, Dr. D. B. St. John Roosa, Dr. Wm. A. Hammond said that those who have devoted their time to the study of nervous diseases know that there is such an affection as hydrophobia, and that it is incurable after it has once become developed in the system. Concerning methods of prevention, he stated that many cases of persons bitten by dogs, supposed to be mad, had come under his observation, and that in each instance he had immediately taken steps to ascertain whether or not the animal which had inflicted the bite was really suffering from hydrophobia. But whether this could be done or not he excised or cauterized the bitten part, first having applied the cupping glass, or caused the patient or some one else to apply his lips to the wound and suck out the poison. Provided that there was no abrasion of the mucous membrane of the mouth, this was unattended with danger to the person doing it. He also applied ligatures when this was possible; and he said that when all these precautions had been taken within a reasonable time after the patient had been bitten he had never known hydrophobia to develop. Believing that the disease could be communicated to a human being only by means of the saliva, he had always held that this was not possible through the blood. He has inclined, therefore to doubt the efficiency of Pasteur's method of inoculation; but at the same time he did not feel at present that he was in a position to express a definite opinion in regard to the matter.

Dr. Hammond quoted the statistics of 534 reported cases of hydrophobia, which showed that in 353 of these the lapse of time between the bite and the development of the disease was less than three months; while in only 30 was it more than six months. He believed, therefore, that the stories of persons being attacked by hydrophobia years after having been bitten were altogether mythical; and contended that there was not on record a single well-authenticated instance in which the patient died from the bite of a mad dog a year after having been bitten. Not more than one-third of the persons bitten by dogs actually affected with the disease contracted hydrophobia. In the case of the Newark children there was no proof that the dog had it, and there had been much useless agitation in the community regarding the matter. Dr. C. L. Dana, A. H. Smith, T. E. Satterthwaite and F. R. Sturgis also took part in the discussion.

Miscellany.

"GOD SAVE THE ALUMNI ASSOCIATION OF COOPER MEDICAL COLLEGE."

The *Pacific Medical and Surgical Journal*, confused, no doubt, by the similarity of its title to that of this *Journal*, reproduces in a recent issue, two of our editorial articles without credit. Sedulous to

avoid falling into a similar error, we take pleasure in acknowledging our indebtedness to our contemporary for the report of a presidential address before the Alumni Association of Cooper Medical College, which contains, couched in the elevated diction of the Occident, a remarkable tribute to the medical profession in general, and to the founder of the College in particular.

"Every man entering into and acting up to the tenets of the medical profession," we are told, "is elevated inestimably above the rest of mankind, because it not only affords the opportunity of doing good, which is nothing in comparison to the other virtue it permits us to acquire if we possess it not, namely, the ability to suffer the grossest ingratitude from man, and the vilest slander from garrulous woman and be resigned. How few of us would ever have been able to possess this immense privilege, if there had existed no one to found a medical college at the time Professor E. S. Cooper conceived the idea of undertaking the immense task, which he brought to so successful an issue."

The gentlemen assembled on this occasion had met for six years as the Alumni Association of the Medical College of the Pacific, but on the demise of that institution, they convened to start the alumni institution of Cooper Medical College, "the young giant, rising pure and mighty." It is a little difficult to see how the death of the alma mater, even if she were less pure and mighty, should constitute her sons at once alumni of the young giant. Some filial reminiscences are indulged in of the impurer and feebler institution, and of the peaceful days before the plunge was made by her sons into the "raging, seething vortex of practice in which many, many sink, never to rise." It is pointed out with considerable plausibility that "It would be unnatural, were we to witness the demise of our dearest friend without experiencing the deepest regret." Also, that: "It is impossible to stand at the bier of a departed friend without anguish."

But after thus setting up the bier for the departed, the orator turns with new courage to worship the rising luminary. *Le roi est mort: vive le roi.* "The Alumni Association of the Medical College of the Pacific is dead; God save the Alumni Association of Cooper Medical College!" To which latter aspiration may we be permitted earnestly to add, "Amen!"

ACTION OF SUNLIGHT ON MICRO-ORGANISMS.

AT the meeting of the Royal Society, on January 14th, reported in the *Lancet*, January 30, a paper on the "Action of Sunlight on Micro-organisms," was read by Dr. Downes, Medical Officer of Health for the Chelmsford combined districts. In previous papers to the Society in 1877, 1878, and 1879, the author, conjointly with Mr. T. Blunt, showed that sunlight was fatal to saprophytes by a process of hyperoxidation thereby induced. In this process, the more refrangible rays were the most active. In the course of the research, two other facts of importance also came out. It was found that in the presence of free oxygen, the molecule of oxalic acid might be entirely resolved into water and carbonic acid by the action of light, more especially of the more refrangible rays; $C_2O_4H_2 + O = 2\,CO_2 + H_2O$. Further, it was discovered that the alterative ferment of cane sugar (a representative of the singular and important bodies, the diastases, which play so important a part in animal and vegetable economy), was oxidized by sunlight. These investigations have not, as yet, been repeated as a whole, but each point put forward in them has now been confirmed by independent observers.

After a reference to the results obtained by Professor Tyndall in 1881, and by others, the author summarizes the recent work of Professor E. Duclaux, who finds that micrococci are apparently far more sensitive to sunlight than the spore-forming bacilli. Dr. Downes and Mr. Blunt, in their original memoirs, had noted the variation of resistance of different organisms — for example, of the hypho- and saccharo-mycetes — as compared with the ordinary putrefactive bacteria; and the former now describes a specially resistant form of bacterium, resembling, but not identical with, the ascobacteria of Von Teighem. Duclaux coincides with Downes and Blunt in regarding the process as an oxidation, and confirms their results as to the destruction of diastase by sunlight.

In refuting the conclusions of Dr. Jamieson, an Australian observer, that the injurious effect of sunshine on micro-organisms is simply a result of heat, Dr. Downes gives an account of recent experiments of his own, which indicate that a similar action, though, of course, in a less degree, is exercised by diffused light. He concludes with a reference to the well-known observations of Pringsheim on the destruction of vegetable protoplasm by light, and claims them as evidence of the truth of his former generalization that the hyperoxidation of protoplasm by light is a general law, from the action of which living organisms are shielded by a variety of protective developments of cell wall, aggregation of tissue or coloring matter, and in other ways.

POISONING AN INFANT BY ITS MOTHER'S MILK.

AT the August meeting of the Medico-Legal Society of France, an interesting case of arsenical poisoning of an infant by *M. Brouardel* was presented which is thus reported in the *Medico-Legal Journal:* —

A man having failed in an attempt to purloin property from his wife and stepmother, was suspected of having attempted to poison his wife with *arsenic*, and of having caused the death of his nursing child.

The child had what appeared to be an attack of cholera infantum, several days after the mother had been similarly attacked. As it was in the hot season, nothing unusual was thought of it. In November following, the mother and stepmother was similarly affected, when suspicion fell upon the husband.

The wife claimed to have found a white powder in his pocket, which proved to be arsenic acid (1. acide arsenique.) Being called, I decided to bring the body of the child to Paris, exhumed after it had been buried six months.

Decomposition was so far advanced that I was unable to dissect the viscera, and it was therefore necessary to analyze the entire cadaver.

Its weight was two and one-half kilog. and it contained five millig. of arsenic.

I was convinced that the arsenic did not come from the linen around the body, or from the earth surrounding the coffin.

It was necessary, also, to determine how far the arsenic could be eliminated from the mother through

her milk — a subject that had not been seriously studied at that time.

M. Gabriel Pouchet made some very conclusive experiments in that line. He gave to some nursing mothers in the Hôpital Saint Louis, some drops of Fowler's solution (2–12), and found that under these conditions the mother's milk contained a relatively considerable quantity of arsenic. Thus the milk of one mother, who took eight millig. per diem for six days, contained one millig. per one hundred gr. But this does not prove that it would have shown the same results if the arsenic had been given in a large dose, and there was no definite way to clear up this point, except by tests upon the female of animals, and even these experiments were not conclusive, as animals presented extremely variable susceptibility to arsenic.

It was ascertained by these researches that milk is a channel with decided predilection for arsenic, and that it would not be prudent to administer this agent to nursing mothers.

In the particular case in question, I certified that the body of the infant contained enough arsenic to kill a child a year old, and that it was probable, but not positive, that the vehicle by which the arsenic was communicated to the child was the milk from its mother's breast.

Neither the defence nor the prosecution seemed to comprehend what was fairly inferrable from this decision, and the man was condemned to twenty years hard labor.

Correspondence.

HUMANIZED VIRUS.

MR. EDITOR, — As Dr. Chapin started this discussion, I must claim my privilege of bringing it to a conclusion, although I desire to add but little to what I have already said. The position taken by him is, that we must accept as a thoroughly proved fact the startling proposition that, owing to some occult influences peculiar to the locality, the long humanized virus of vaccinia has been preserved in Providence in a state of almost pristine excellence unparalleled in any other part of the known world. One must not for a moment question this because forsooth by so doing he casts a doubt, not upon the impossibility of any chance of error, but upon the personal veracity of certain local health officers, for whose infallibility Dr. Chapin vouches. Any argument based upon universal experience and the writings of the most eminent observers is to have no weight whatever. Certainly no farther discussion is possible under these conditions. I do not expect or wish any one to take my individual dictum in this matter. There in nothing novel or original in what Dr. Chapin is pleased to call my "unfounded assertions" and "gratuitous assumptions," as a very cursory study of the authorities will show. The matter at issue does not in the slightest degree affect my "business," nor shall I ever permit myself to be driven from the discussion of a purely scientific question by any such ungenerous slurs.

Very respectfully,

27 Dudley St., Feb. 13, 1886. S. C. MARTIN, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 6, 1886.

Deaths reported 1,994: under five years of age 684; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 262, lung diseases 311, consumption 302, diphtheria and croup 131, scarlet fever 38, typhoid fever 21, whooping-cough 21, diarrhœal diseases 19, malarial fever 13, erysipelas nine, cerebro-spinal meningitis four, measles two, puerperal fever two, small-pox one, typhus fever one. From whooping-cough, New York 11, Brooklyn four, Baltimore and Charleston three each. From diarrhœal diseases, New York eight, Brooklyn four, Boston and New Orleans two each, District of Columbia, Nashville and Cambridge one each. From malarial fever, New York four. Baltimore three, Philadelphia and Brooklyn two each, New Orleans and District of Columbia one each. From erysipelas, New York and Brooklyn three each, Boston, Cambridge and Northampton one each. From measles, New York and Baltimore one each. From puerperal fever, New York and Baltimore one each. From typhus New York, one each. From small-pox New York one.

In 109 cities and towns of Massachusetts, with a population of 1,226,634 (population of the State 1,941,465), the total death-rate for the week was 14.25 against 16.59 and 18.23 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,033,817, for the week ending January 23d the death-rate was 22.4. Deaths reported 3,906: infants under one year of age 869; acute diseases of the respiratory organs (London) 477, whooping-cough 159, measles 100, scarlet fever 38, diphtheria 38, diarrhœal 31, fever 38, small-pox (Liverpool) three.

The death-rates ranged from 10.4 in Birkenhead to 30.4 in Preston; Birmingham 23.4; Blackburn 30.0; Hull 21.8; Leeds 22.9; Leicester 16.1; Liverpool 26.3; London 21.9; Manchester 24.9; Nottingham 26.1; Portsmouth 20.7; Sheffield 23.0.

In Edinburgh 19.3; Glasgow 28.9; Dublin 29.6.

For the week ending January 23d in the Swiss towns, there were 40 deaths from lung diseases, consumption 33, whooping-cough eight, small-pox seven, diphtheria and croup seven, malarial fever one, typhus fever one.

The death-rates were: at Geneva 22.2; Zurich 15.3; Basle 17.0; Berne 31.0.

The meteorological record for week ending February 6, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Feb. 6, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 6, 1886, TO FEBRUARY 12, 1886.

TILTON, HENRY R., surgeon and major (Fort Wayne, Mich). Granted leave of absence for two months, to commence on or about March 1, 1886. S. O. 8, Division of the Atlantic, February 9, 1886.

BROWN, H. E., major and surgeon. Granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Department of the Missouri. S. O. 29, A. G. O., February 4, 1886.

WHITE, ROBT. H., captain and assistant surgeon. Granted two month's leave of absence, to take effect when his department commander may think proper. S. O. 29, A. G. O., February 4, 1886.

SHANNON, WM. C., captain and assistant surgeon. Ordered for duty at Fort Warren, Mass., relieving Assistant Surgeon John M. Banister, who will return to his proper station (Fort Adams, R. I.) S. O. 27, Department East, February 6, 1886.

EDIE, GUY L., first lieutenant and assistant surgeon. Ordered for field duty in New Mexico with troop "K," 8th Cavalry. S. O. 23, Division of the Missouri, February 8, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE THREE WEEKS ENDING FEBRUARY 6, 1886.

BENNETT, P. H., assistant surgeon. Died at Detroit, Mich., February 3, 1886.

WATKINS, R. B., assistant surgeon. To proceed to Detroit, Mich., for duty, February 3, 1886.

PETTUS, W. J., assistant surgeon. Appointed an assistant surgeon, February 5, 1886. Assigned to duty at New Orleans, La., February 6, 1886.

RESIGNATIONS.

H. J. Bigelow, M.D, has resigned his position as surgeon to the Massachusetts General Hospital. His resignation has been accepted by the trustees and he has been made surgeon emeritus with five beds placed at his disposal.

George C. Shattuck, M.D, has resigned as visiting physician to the Massachusetts General Hospital and has been appointed consulting physician.

APPOINTMENTS.

A. T. Cabot, M.D. and M. H. Richardson, M.D., have been appointed visiting surgeons to the Massachusetts General Hospital.

THE LATE DR. F. H. LOMBARD.

At a meeting of the Obstetrical Society of Boston, held February 13, 1886, the following minute was unanimously adopted and ordered to be spread upon the records:

The Society wishes to express its deep sense of loss in the untimely death of Dr. Frederic Howard Lombard. Only a few weeks have elapsed since his unanimous election to membership; but on two occasions he presented to the Society, by invitation, communications of more than usual value and interest. These papers evinced his marked abilities as a careful and intelligent observer, a conscientious practitioner, and a clear and vigorous writer.

He was especially interested in the pursuit of those departments of medicine, the knowledge of which it is the object of this Society to cultivate, and after a careful preparation at home and abroad he had already achieved success in the practice of his chosen specialty.

He held appointments at the Boston Dispensary and the Free Hospital for Women, and had rendered material service to the Boston Lying-In Hospital, with which during two summers he was temporarily connected. He was much interested in the teaching of obstetrics, and his work in that department of the Summer School was conducted with the same ability and success which characterized his other undertakings.

Manly, courteous, kindly, and upright in all his dealings, he was beloved by his patients and respected by his professional brethren.

SOCIETY NOTICES.

NORFOLK DISTRICT MEDICAL SOCIETY.—A meeting for Scientific Improvement will be held at Room 7, Palladio Hall Building, corner of Warren and Dudley Streets, Roxbury, February 23d, at 7.45 P.M. Communications: I. "A Case of Femoral Aneurism," C. A. Bemis, M.D. II. "Epistaxis, with Cases," C. W. Sparhawk, M.D. Members of other Districts are cordially invited to be present and participate in the discussions. Refreshments will be served after the meeting.

S. ALLEN POTTER, M.D., *Secretary*.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting will be held at 19 Boylston Place, Monday, February 22d, at quarter of eight, P.M. Reader: Dr. F. W. Hooper. Subject: "Adenoid Vegetations in the Naso-Pharyngeal Cavity." Report of the Committee appointed in consequence of Dr. Field's paper on "The Appointment of Medical Examiners." Medical Examiners of Massachusetts are invited to be present.

E. M. BUCKINGHAM, *Secretary*.

A CASE OF CONGENITAL CAVERNOUS LYMPHANGIOMA OF THE BACK.

BY C. B. PORTER, M.D.,
Surgeon to Massachusetts General Hospital.

THE patient, an infant four months old was brought to my office for examination and advice. Three pedunculated tumors were attached to the median line of the back between the third to sixth dorsal spines. One was the size and shape of a large sausage with narrow pedicle springing from near the middle. The other two were much smaller and more sessile. All were soft and more or less compressible, apparently giving slight impulse during crying, producing pain when handled as evinced by crying. The two smaller ones translucent, the larger one dark and dusky. The mother stated that this had been translucent, but of late had become dark and angry looking, and much more sensitive when the child was bathed or moved, and it looked at one point as though it was about to ulcerate. The normal skin extended a short distance up the pedicle and then ended in a distinct line, the sac of the tumors looking like thickened serous membrane. The child was so fat that it was impossible to determine whether or not the arches of the vertebræ were incomplete. There was no paralysis, the child making all motions in a perfectly natural manner. The bodily functions unimpaired.

The child breathed, nursed, slept, urinated and defecated in a healthy manner. The mother stated, however, that the child was becoming more and more peevish, crying when the larger tumor was handled, and that it seemed more sensitive than at first, and that the color had changed.

Recognizing the uncommon seat and also the rarity of multiple character of the deformity, I nevertheless thought that I had to deal with multiple spina bifida. The character of the sacs; their translucency; the compressibility, the contents apparently receding under pressure causing crying, and redistension. All combined made it probable that there was a communication with meninges of the cord. The friends desired operation, understanding fully the dangers. I consented to operate, fearing that the large tumor was soon to open by ulceration of the sac. The two important indications were:

First, to prevent draining away of the cerebro-spinal fluid, and to meet this I proposed to ligature the pedicle subcutaneously by silver wire.

Second, to prevent extension of the inflammation from wound to meninges, this to be prevented as far as possible by thorough antiseptic precautions.

The operation was performed October 16, 1884. The child being etherized, the largest tumor was surrounded at its base by a silver wire passed subcutaneously; this was twisted tight. The tumor was then punctured by a small trocar to draw off and preserve the fluid. Very little fluid escaped, but by firm pressure a few drachms were evacuated. The tumor was then cut off, no fluid escaped from the proxinal end of the pedicle. The skin was brought together by silk sutures making a linear wound about one and one-half inches long. The two smaller tumors were treated in like manner except that the pedicles were so near together that they were both included in the same wire ligature. The wounds were treated in the most thorough antiseptic manner throughout, dressed with iodoform and carbolic gauze, with compression. The child did well up to the eighth day. The silver ligatures were removed on the fourth day, the superficial wounds having united by first intention except a small part of one, all sutures removed the seventh day. On the eighth day the child commenced to have frequent painful discharges from the bowels, the milk being passed in small lumpy curds undigested with mucus and some streaks of blood, marked tenderness of abdomen. The thighs drawn up, complete anorexia, the child refusing the breast most of the time. This condition continued with more or less amelioration till the twelfth day, when the child died exhausted. The wounds were healed except a small granulating surface size of a pea bean. There were no convulsions. The cause of the muco-enteritis of which the child died, seemed to me to be due possibly to some change in the mothers' milk, induced by care, anxiety for the well being of the child and loss of sleep, as she insisted on being almost constantly with the child, holding it most of the time in her lap, although a nurse was in attendance desirous of relieving her. Dr. Belt, of South Boston, very kindly saw the child a number of times with me and in my absence Dr. Gannett examined the tumors and reports them to be typical cavernous lymphangiomata.

TWO CASES: OPERATION FOR THE CURE OF SPINA BIFIDA; AND FOR THE RADICAL CURE OF HERNIA.[1]

BY E. H. BRADFORD, M.D.,
Surgeon to Boston Children's Hospital.

THE patient was a fairly-nourished infant five months old, presenting a cystic tumor in the lower cervical region. The tumor presented all the characteristics of a spina bifida, which did not increase when the child cried, and did not diminish on pressure. The inference was that the communication, if any, with the spinal cord was small. The tumor was stationary, but the walls were thin and were beginning to ulcerate. As the pedicle was long, it was decided to attempt amputation according to the method suggested to me by Dr. Porter.

A silver wire was passed subcutaneously around the pedicle, using for the purpose a long, curved needle, with a handle and an eye at the point. Little difficulty was encountered in passing the wire, and the sac was not punctured. On tightening the wire, however, the end was twisted off, and it was found that a small opening remained. This was closed by a catgut suture through the pedicle after amputation of the sac. No new filaments were found in the sac.

The wound was dressed antiseptically with corrosive gauge, and no leakage took place for three days. On changing the dressing, however, at the end of that time, a slight amount of serous fluid was found exuding. The patient was quiet after the operation, but became quite restless after twenty-four hours, and died without convulsions at the end of four days without symptoms of meningitis. The temperature was slightly elevated until the day before the patient's death, when it became sub-normal — 98°.

[1] Read before the Suffolk District Medical Society, Surgical Section, February 4, 1885.

[1] Read before the Suffolk District Medical Society, Surgical Section, February 4, 1885.

The case presented difficulties and demanded an operation, as rupture of the sac was imminent. It was impossible to determine positively whether a direct communication persisted with the cord, but it was inferred that no such communication did exist or was minute.

The statistics appear to show that Brainard's method of abstraction of a certain amount of fluid by aspiration, and the injection of a certain amount of iodine (iodine pure, 0.5; iodide of potash, 1.0; distilled water, 30.), promises success in a certain number of cases.

Löbker reports a case of cure of a case of lumbar spina bifida. The case was operated on three times, at five to eight days' interval; five grains of fluid was abstracted, and two grains of solution of iodine injected. The child was entirely well a year and a half later, and the tumor had shrivelled and disappeared, except that a growth of hair marked the spot.

Löbker [2] also reports a successful amputation after tying the pedicle in a child five days old, the case being one of lumbar spina bifida. Also, a second case of death following the same operation.

The statistics collected by Wernitz in 153 cases were as follows:—

Treatment.		Cured.	Died.
Compression	4	4	0
Puncture	57	17	40
Injection	55	42	13
Ligature	16	10	6
Incision	5	2	3
Excision	8	6	2
Amputation	5	4	1
Plaster	3	1	2
	153	86	67

Tabular statements of this sort, however, are manifestly of little value.

Mr. Holmes [3] justly states that no case of spina bifida should be subjected to operation, except in most urgent circumstances, and prefers injection, the American method, the sac not being emptied before the injection of the iodine, to the French method, where iodine is used as in a hydrocele. The pedicle should be compressed during the injection, and the fluid is sometimes allowed to flow out.

As death in these cases, is threatened more from direct exhaustion rather than from meningitis, and the exhaustion appears [4] to be largely induced by a loss of cerebro-spinal fluid, it would seem that Dr. Porter's method offers, as the leakage of the fluid is prevented, a more reasonable chance than either direct amputation or excision, and it is decidedly more surgical than the method of clamping the pedicle, or ligaturing the skin, as well as the sac.

OPERATION FOR THE RADICAL CURE OF HERNIA.

J. H., a boy two years and two months old, presented a congenital hernia of large size (size of a small peach). He was sent to the hospital by the Society of Prevention of Cruelty to Children, on account of abuse by his parents, and for the purpose of having his hernia cured. Treatment by truss, or the injection of white-oak bark not being feasible, on account of the lack of care in after-treatment, a radical operation was determined upon. The method introduced by Mr. Banks, of Dublin, was decided upon. This consists of twisting the sac after reduction of the hernia, and using the twisted folds of the sac to act as a plug in the ring, a suture being passed through the pillars and the twisted sac to prevent the plug from untwisting.

A free incision was made down to the sac, reaching from above the external ring to the scrotum. The sac was then cleared at its middle, and a ligature passed around the sac, but avoiding the cord. This latter procedure required careful dissection, as the parts were, in a child of that age, very thin and delicate. The ligature (catgut) was then tied and the sac cut off above, the lower portion serving as a tunica vaginalis. The upper portion of the sac was freed by stripping as far as was possible, up to the ring, and was then gently twisted. A silk suture was then passed through the pillars and twisted sac, and tied. The free end of the sac was then rolled up, and stitched as an extra wad. The skin wound was closed with catgut sutures.

Thorough antiseptic dressings were impossible, owing to the child's urine, but the wound was kept covered with iodoform. The skin did not unite by first intention, but gaped completely, and the boy's temperature rose to 104°, and his condition for ten days seemed alarming. At the end of a fortnight, however, the temperature was permanently normal, and the wound well in progress of cicatrization. At the present time, the child's wound is completely healed, and the opening is entirely closed, and though the child cries, and runs about without a truss, the hernia is kept well up.

A CASE OF PISTOL-SHOT WOUND OF THE HEAD RESULTING IN ABCESS OF THE BRAIN, WITH A REPORT OF THE AUTOPSY.[1]

BY ROYAL WHITMAN, M. D.

ON October 16, 1884, I was called to attend the patient whose history, as I afterwards learned, was as follows:

He was fifty-seven years of age, born in Ireland, and had never suffered from any severe illness. He had had much trouble in his family affairs, but of long duration; and there appears to have been no especial cause for anxiety, financially or otherwise. He occupied a responsible position in a large establishment, where he had been employed for twenty-six years; and, until a week before his attempted suicide, nothing unusual had been noticed about the man mentally or physically. At this time he left work, ostensibly on account of a cold; but the real reason appears to have been mental depression. Daily visits were made him by various employés, at the request of the firm; and, on this particular morning, a report had been made that he was in a very depressed state. Shortly after, having dressed himself in new underclothing, he shot himself in the right ear with a revolver of 32 caliber, the final exciting cause having been, it appears, the failure of the furnace to draw.

On my arrival, I found him lying on the bed, his shirt saturated with blood which was slowly flowing from a ragged wound in the right ear just above the external auditory meatus. He was conscious, pale, with a pulse of 80, of fair strength.

Ether was given; and, after shaving the right side of the head, an irregular body could be felt under the scalp, at a distance of about three inches above the meatus. This was cut down upon; and I

[1] Read before the Suffolk District Medical Society, Surgical Section February 4, 1885.

extracted what I supposed to be the greater part of the bullet, flattened out to about the size of a five-cent piece, with rough, rolled-up edges. The temporal muscle was considerably lacerated and blackened, and several small fragments of lead were removed from the vicinity. On passing my finger down the track of the ball, the temporal bone appeared to be slightly depressed; and I thought that I could detect several fissures in its surface, which was still covered by a portion of the muscle. On examining the ear, it was found that the ball had entered the concha just above the meatus; and, from this opening, several radiating tears extended, through which the cartilage projected. The ridge of bone about the upper portion of the meatus was bare, and the cartilaginous canal of the ear partially separated and slightly depressed from it. It seemed clear at the time that the ball, entering, had struck the firm wall of bone just above the meatus; had flattened and passed upwards, fracturing the squamous portion of the temporal bone.

Several bleeding vessels were ligated, a seton introduced through the track of the ball, and pressure applied over this area, which practically controlled the bleeding, though a slight oozing continued during the following night. In the afternoon the patient signed a transfer of property, and a will, making comments on the latter, as it was read to him. During the night and the several succeeding nights his mind wandered at times, and he was restless and sleepless, for which various sedatives were given. On the following morning the hæmorrhage had ceased, and the wound was irrigated with a solution of corrosive sublimate, and dressed with corrosive-sublimate fomentations. During the following week there was but a slight discharge from the wound, the seton was entirely removed on the fifth day, and the upper wound closed soon after, the treatment consisting of rest in bed, milk diet, ice bag on head, and cathartics. The patient complained of no pain, his mind seemed clear but weak, and his memory much impaired. He had no recollection of shooting himself, but concluded that he had been injured by a fall, and was utterly unable to understand why he had not put a pistol to his ear, and blown his brains out, as he had intended. All the acute symptoms connected with his injury having subsided, I now advised his removal to the McLean Asylum, as his mental power was considerably impaired; and, if he was to recover, as seemed probable, it would be advantageous to him to have it understood that his attempted suicide was caused by temporary insanity; and he accordingly entered there, on October 25th, at his own request. For the further details of the case, I am indebted to Dr. Cowles.

October 30th. It was noted that his memory was poor and he was very voluble. There was at this time a moderate discharge of pus from about the ear. The wound was treated by daily irrigation with a solution of carbolic acid and carbolized compresses, and the patient kept in bed.

November 3d. He sat up for the first time and seemed rather depressed.

November 12th. There seemed to be a slight improvement in his mental condition.

November 18th. Necrosed bone could be felt for three-fourths of an inch above and about the meatus. His temperature was taken at this time, showing it to be below normal.

November 23d. He discovered a scab on his head, over the cut made for the removal of the ball, and talked about it incessantly, insisting that it was the "barbers' itch," showing marked mental weakness.

November 24th. He was dressed for the first time, and for the two following weeks there was but little change in his mental condition, his memory being much impaired. His appetite was good, his bowels obstinately constipated, necessitating the administration of various cathartics, while his general physical condition seemed to have improved somewhat.

December 7th. Seven weeks after the injury, he first complained of frontal headache, which continued a prominent symptom until his death; and for the several succeeding nights was restless, disturbed the other patients by talking to himself, and during the daytime by repeating the same stories over and over again. Altogether there seemed to be such a mental failure that he was removed to another ward.

December 15th. Dr. Hodges was called in consultation in regard to the rather extensive area of necrosed bone about the ear, but advised non-interference, there being at this time, a moderate, free discharge of pus from the meatus and the neighborhood. The hearing on this side was tested several times, but seemed to be perfect.

December 19th. About an hour after the ear had been syringed and dressed as usual, there was a sudden further discharge of a teaspoonful or more of pus from the ear, which the nurse described as being thinner and darker than usual. The patient became faint, vomited, and when he was put to bed, it was noticed that he dragged his left foot.

On examination, it was found to be very difficult to make him understand simple questions. He seemed stupid and dazed. Called the physician by his daughter's name, and the nurses by the names of his various friends. The movement of the left leg and the grasp of the left hand were feeble. The left side was cooler than the other, and the sensibility to touch diminished. On the following morning, he lay in bed in the same stupid condition, from which he could with difficulty be aroused.

December 21st. Compressed sponges were placed in the meatus for the purpose of dilating the canal, and for the few following days, he appeared brighter, though the paresis of the left side continued and increased.

December 28th. The paralysis of the left side was now complete, and the patient lay in a deep stupor. A twitching of the muscles of the paralyzed arm was noticed, and the discharge of pus from the ear ceased. The patient now would not swallow, and nutritive enemas were given.

December 31st. Dr. Hodges called. The face was now drawn to the left and the patient comatose. On passing a probe into the auditory canal, necrosed bone could be felt all along the upper boundary and the probe passed in a direction upward and inward for two inches, then striking upon a yielding substance, apparently the dura.

January 1st. Conjugate deviation of the eyes to the left was noticed, and during the afternoon, the patient died, seventy-seven days after the injury.

The following is the report of the autopsy, which was made by Dr. Gannett:

"Autopsy made fifteen hours after death. Body well developed and nourished. Slight lividity of dependent portions. Ratio of head to body, and of cranium to

face, apparently normal. Ant.-post.-diameter of skull, 18.8 cm.; transverse, 13.9 cm.

"From the right ear, a thin, foul, puriform fluid exuded. On the removal of the scalp, the pericranial tissues just behind the right ear, about one cm. below its upper border, were discolored, bluish-black over an area two cm. square, from the centre of which numerous small granules of lead were removed. The temporal muscle showed a similar bluish discoloration, and was considerably depressed below the level of the surrounding bone substance. In the middle of the right temporal bone, was a depressed, comminuted fracture twenty-five by thirty cm. in diameter, some portions near the centre being loose, those on the periphery being, for the most part, adherent to the surrounding bone. About the edge of the fracture, several minute fragments of lead were imbedded. The inner surface of the tabular portion of the right temporal bone showed a series of comminuted fractures, with elevation of fragments. About one cm. from the vertical portion, was an opening in the petrous portion, which communicated, both with the meatus and with a fistulous track lying just above the meatus.[2]

"The calvaria showed no noteworthy appearances; freely separated from the dura. The dura on the right side showed numerous bluish-black patches. On the inner surface of the dura, were numerous dark patches, elevated about one mm. above the surface, which could not be washed or scraped off. The pia over the convexity of the right hemisphere had a slightly yellowish tint, and on pressure, this half of the brain fluctuated. On removal of the brain, it was found that the dura was intimately adherent to the pia over the seat of fracture in the right temporal bone already described. Just beneath this adherent portion of the dura, in the right temporal lobe, were two cavities, one the size of a large English walnut, with sharply-marked, smooth walls of connective tissue, about one mm. thick, just outside which could be seen brain substance, showing nothing abnormal beyond a series of small, dark-red points following the course of this wall. The other cavity was the size of a plum, its contents consisting of softened, yellowish brain substance. To the outside of this cavity, for a distance of nearly two cm. in all directions, the brain substance was softened, moist, of a pale-yellow color, resembling baked custard. Above, and to the inside of these two cavities, was one of an irregular shape, nearly as large as a peach, situated in the white matter of the temporal, lower parietal, and anterior occipital lobes, also involving the whole of the posterior third of the nucleus lentiformis, and a portion of the contiguous inner capsule. This cavity contained rather soft blood-clots, the brain surrounding it being softened and of a gray color, with abundant punctate hæmorrhages. The remaining portions of the brain were quite firm and showed nothing remarkable." The sinuses of the dura were everywhere free.

The examination of the body having no particular bearing on the case, has been omitted.

The case presents, I think, one or two points of interest:

(1) The complete smashing of the ball into so many different fragments, a rare occurrence when a conical bullet strikes a bone with its full initial velocity. In this case, one fragment fractured the squamous portion of the temporal bone, another fractured and penetrated the petrous portion, another lodged in the bone, while the remainder was broken up into the numerous fragments, as described.

(2) The normal or subnormal temperature observed during the whole course of the abscess formation, a symptom of abscess of the brain as yet not fully recognized as of importance as a diagnostic sign. Hulke, in Holmes's "System of Surgery," says that this symptom deserves attention; while Nancrede, in Ashurst's "Encyclopædia of Surgery," says: "I believe that an abscess involving cerebral tissue alone, will be accompanied, in most cases, by a subnormal, or at least, not an elevated temperature. When a high temperature is observed, either the pus-collection is simply a localized suppurative arachnitis, limited by adhesions, or there is a meningitis in addition to the abscess. If originating from bone caries, middle-ear disease, or where the abscess is secondary, there is almost, of necessity, an elevated temperature, although even here, during the height of the symptoms, as in a case reported by Huguenin, the temperature may be normal. If these observations are confirmed by others, a valuable diagnostic point will be afforded."

The sequence of events in this case, seems to have been 1st, Fractures of different portions of the temporal bone with contusion of the brain. Then inflammation of the membranes and formation of an abscess, the symptoms of which were almost latent until December 7th, when the symptom of headache became prominent. On December 19th, the abscess burst, partially evacuating itself through the meatus, the sudden disturbance of the cerebral tension resulting in the dizziness and vomiting which followed the discharge of pus. The second abscess then formed, with implication of the deeper structures of the brain, as shown by the rapidly-increasing paralysis and stupor, finally resulting in the hæmorrhage, which appears to have been the immediate cause of death.

All authorities agree that it is extremely difficult to make an early diagnosis of chronic abscess of the brain, particularly, when, as in this case, it was situated in the temporal lobe, which is not directly connected with sensibility or mobility.

Looking at this case after the autopsy, the symptoms appear to have been almost typical of an abscess in this region.

(1) A cause for the abscess existing.

(2) Mental weakness and loss of memory, though these symptoms might have been explained by a supposed mental disease, which caused his attempted suicide.

(3) Persistent headache during the last months, which a localized meningitis might have caused.

(4) Constipation.

(5) A normal or subnormal temperature and slow pulse, the former not, as yet, a fully recognized symptom of abscess, and finally, paresis, stupor, and death.

In regard to abscess of the brain in general, authorities practically agree that it is impossible to decide before an operation, whether or not an abscess is complicated with a meningitis. That an abscess following an injury of the skull is usually situated in that portion of the brain immediately beneath it, and that having made a diagnosis of abscess, the only possible remedy is in the evacuation of the pus.

With regard to trephining, the following rules appear to be generally agreed upon by the various writers on the subject:

If an injury over the motor region has been

[2] On section of the bone another fragment of lead was found firmly embedded in the fractured posterior or wall of the tympanic cavity.

followed by symptoms of abscess, with paresis or paralysis of the opposite side, uncomplicated with anæsthesia, the prospect of evacuating the pus and relieving the symptoms would be good, the extent and completeness of the paralysis being an important element in the prognosis.

The prognosis would be much graver, and the operation possibly contra-indicated, under the following conditions:

(1) If the paralysis was on the same side as the injury, showing a probable implication of the opposite side of the brain, in which case it would be useless to trephine over the original injury.

(2) The combination of anæsthesia with the paralysis, showing a lesion of the white substance of the brain, or of the internal capsule, too extensive to be relieved by an operation.

(3) With an injury in the frontal or occipital region, or over the sensory area of the skull, if paralysis occurs, which would indicate an extension to the motor area, or to the deeper parts of the brain. Although, as authorities agree that death is certain if the pus is not evacuated, it would seem that operative interference would be justifiable, even under such adverse conditions.

Having trephined the skull in search of pus, it would seem advisable to aspirate the brain through the dura, or to incise that membrane, whether or not it showed signs of an underlying inflammation. I have found no cases reported where immediate death followed aspiration or incision of the brain substance, while there are many instances where, at the autopsy, abscesses of the brain were found lying under the opening made by the trephine or in the vicinity which were not opened, either because the dura presented a normal appearance, or from fear of incising the brain substance.

Having opened an abscess of the brain, as much attention should be paid to drainage, as in the case of an abscess in any other situation. Cases are reported where the evacuation of the abscess was followed by a temporary relief of the symptoms of compression, and afterwards by death from extension of the abscess, which was not thoroughly drained.

REPORT ON OBSTETRICS.

BY C. M. GREEN, M.D.

THE CHOICE OF METHODS IN ABDOMINAL DELIVERY.

Dr. R. P. Harris,[1] to whose unflagging interest the profession ever looks for light on this subject, gives a terse and lucid *résumé* of the present aspect of abdominal delivery in view of recent improvements in the operation, and tabulates the results of the Cæsarean operation by the new method of Sänger and its modifications during the past five years. Any method by which the uterine wound can be successfully closed is a great improvement on the so-called "old" Cæsarean operation, as has been shown by results in recent cases. But, as Dr. Harris has so frequently and forcibly pointed out, no method of operation, no amount of care in matters of detail, will often result successfully in cases which have been suffered to linger for hours and days undelivered in the vain hope that abdominal section may not be necessary. Delay and futile attempts at delivery are doubtless responsible for many failures in cases wherein timely operation by approved methods would have been successful. "When," says Dr. Harris, "will the accoucheurs of the United States realize the fact that the high rate of mortality lies at their door rather than at that of the operator?"

Sänger's method consists essentially in the resection of a strip of the muscular uterine wall on each side of the incision, whereby a free border of peritonæum can be turned in and its serous surfaces sutured. Spencer Wells has made it familiar that two peritoneal surfaces in apposition unite in twenty-four hours: and this fact was shown in Dr. Drysdale's case, in which death followed the operation in twenty-six hours and the peritoneal surfaces in the line of incision were found united post mortem. It has been found in practice, however, that muscular resection is not always necessary, as in some cases, after the uterus contracts, its serous coat is sufficiently loosened to readily allow the peritonæum to be slid over the edge and turned in. Several methods of suture have been devised by Sänger and others; but they all consist essentially of deep sutures of silver wire passing through the muscular tissue, but not including the decidua, and superficial stitches of cat-gut or silk so introduced as to approximate the turned-in peritoneal surfaces. Unless the uterine tissue is degenerated by disease or unduly long labor, this method ensures persistent closure of the uterus and prevents leakage into the peritoneal cavity. And with the improved methods of antisepsis now so generally employed there is no reason why the operation should not result successfully in a large proportion of cases, if only it is performed while the patient is in a favorable condition. Leopold, who follows Sänger's method with some modification, has saved four women and five children in five operations, a result very largely due to the fact that the operations were timely. Dr. Harris' table includes twelve cases, of which three were in this country and nine in Germany: of this number there were saved 50 per cent. of the women and 83 1-3 per cent. of the children. In five cases the condition was unfavorable at the time of the operation.

The chief obstacle to success in late Cæsarean operations, apart from the generally unfavorable condition of the patient, is undoubtedly the degenerated condition of the uterine tissue, on account of which union will not take place. In delayed cases, therefore, where the obstacle to natural delivery is not in the lower segment of the uterus, Dr. Harris thinks that laparo-elytrotomy deserves to be more thoroughly tested, as by this method incision of the uterus is avoided. The author has tabulated twelve cases of this operation, being all which have been performed in the last fifteen years since Dr. Thomas' first operation. Ten of these cases were in this country, and two in England. Of this number 50 per cent. of the women and 58 1-3 per cent. of the children were saved; but only four cases were considered "favorable" for the operation, and these all recovered and the children were all saved. Unquestionably in this country laparo-elytrotomy has been more successful than the Cæsarean operation.

When the child is putrid, the choice of operation should lie between the Porro-Müller operation and laparo-elytrotomy; but it appears safer to Dr. Harris

[1] American Journal of Medical Sciences, October, 1885.

to select the former method as affording less risk of subsequent septic absorption. The Porro-Cæsarean operation has proved very successful in Milan and Vienna, but quite the reverse in Germany, where the new methods have raised the old operation to greater estimation.

DIAGNOSIS OF THE POSITION OF THE HEAD BY FEELING OF THE FŒTAL EAR.

Lomer,[2] of Hamburg, recalls attention to the value of feeling of the fœtal ear as a means of verifying, in certain cases, the diagnosis of the position of the head. When the medical attendant sees a case of labor early, the diagnosis of position can usually be made by abdominal palpation, and confirmed by vaginal examination of the sutures and fontanelles. It sometimes happens, however, that the patient is not seen until late in the labor, when extensive œdema of the scalp has so obscured the sutures and fontanelles that by their examination no positive opinion can be formed. It is in such cases that instrumental interference is often necessary, and it is a matter of utmost importance that the fœtal position should be accurately made out. The anterior and posterior borders of the ear present such well-marked differences that examination of that member leaves no room for doubt towards which side of the pelvis the occiput is directed. When the head is low in the pelvis an ear can be reached without difficulty: if, however, the head is high, it may be necessary to introduce the half-hand; but as in such cases operative interference is usually indicated, when there is sufficient obstruction to cause enough œdema of the scalp to obscure the sutures and fontanelles, and as the patient would previously be anæsthetized, the examination with the half-hand can be made without difficulty. Where there is room between the head and pelvic walls for the forceps blades, there is room for the tips of examining fingers.

THE TREATMENT OF PREMATURELY-BORN INFANTS.

This subject has deservedly received considerable attention from recent authors; and it is now well known that, if any expectation is to be entertained of rearing prematurely-born infants, great care must be taken to maintain a suitably high temperature and to ensure a properly regulated nourishment. The former desideratum may easily be obtained by the use of either Credé's hot-water cradle or Tarnier's couveuse, the construction and method of use of which are now well understood and which are figured and described in the last edition of Lusk's Midwifery. To ensure a proper amount of nourishment for infants too weak to suck, M. Tarnier, in a recent paper[3] recommends the use of "gavage." The apparatus for practising gavage consists of a soft rubber catheter (size No. 18, Charrière) with a small glass cup fixed to its upper end. This catheter, well oiled, is passed down the œsophagus about six inches, when it may be supposed to have entered the stomach. The nourishing liquid is then poured into the glass cup and allowed to flow into the stomach by its own weight: in withdrawing the catheter it is necessary to do so rapidly, else the fluid may be regurgitated. The number of times in the twenty-four hours in which gavage should be employed and the amount of nourishment to be administered each time are to be determined, of course, by the age and strength of the infant: in general, the feedings should be more numerous and the amount of nourishment given each time diminished according as the age of the infant is less and its vital powers more feeble. When the child is very small and born considerably before full term, eight grammes is a sufficient amount for one feeding. Tarnier has used asses' milk with success; but of course human milk is to be preferred. In some cases the infant is sufficiently strong to suck in part, and the breast feeding can be combined with gavage. By the use of the couveuse and gavage, Tarnier has successfully reared two infants which were born soon after the sixth lunar month, and he does not altogether despair of rearing children born even before that time.

THE EFFECT OF FULL HOT BATHS IN EXCITING LABOR PAINS.

Led by the successful experience of Breus,[4] in the use of hot baths in the treatment of nephritis and eclampsia in the pregnant and puerperal conditions, Sippel,[5] of Frankfort, tried Breus' method in two cases, with the following interesting results: —

The patients were advanced to the thirty-second and thirty-fifth weeks of pregnancy: in both, albuminuria with scanty urine, œdema, nausea, vertigo and other symptoms foreboded eclampsia: neither patient as yet had labor pains, in both the fœtal pulse was normal. Both patients were put into a full hot bath at a temperature of 110° F.; kept there for twenty minutes, and then wrapped up in hot, moist blankets and subjected to profuse diaphoresis. Shortly after the removal from the bath uterine contractions set in. In one patient the pains continued and a living child was naturally delivered fourteen hours after the beginning of the bath: there was no hæmorrhage, the puerperium was normal, and the urine was free from albumen on the tenth day. In the other case the pains ceased after an hour and a half; but on the next day a second bath was given in a similar way, and forthwith pains set in which continued, and ten hours after the beginning of the bath a living child was spontaneously born. There was no hæmorrhage, the convalescence was normal and albumen disappeared from the urine within five days.

In the two cases in which Breus had used the hot-bath treatment during pregnancy, for the relief of uræmic symptoms, premature labor did not ensue: and Breus expressly states that this treatment may safely be employed during pregnancy, in cases of threatened eclampsia, without fear of inducing premature labor. This difference in results Sippel attributes to the fact that Breus in his cases gave chloral freely by rectum, which drug so diminished the reflex sensibility of the peripheral nerves that the hot baths did not excite labor pains. Premising that a like reflex irritability exists in the healthy gravida as in the pregnant woman suffering with nephritis, Sippel believed that if this irritability were not obtunded with narcotics, the hot bath might prove a valuable means of inducing premature labor, when for any reason that operation was indicated. An opportunity for testing his theory presented itself in the following case:

A secundi-gravida with a generally contracted pelvis having a diagonal conjugate of 4.2 inches, and who had advanced to the thirty-fifth week of pregnancy, was to

[2] Centralblatt für Gynäkologie, No. 35, 1885.

Am. Jour. Med. Sciences, January, 1886.

[4] Vide Vol. cix., No. 2 and Vol. cx. No. 2, of this Journal.
[5] Centralblatt für Gynäkologie, No. 44, 1885.

have labor induced in the interest of the child. She was placed in a full bath at a temperature of 106° F., which was raised with tolerable rapidity to 110°: she remained in the bath twenty minutes, towards the end of which time slight pains set in, but soon disappeared. As there was no occasion to employ diaphoresis, the patient was then allowed to attend to her usual occupation. On the next day she received a second bath under similar conditions: slight pains ensued; but they soon ceased. On the following day she was placed in a third bath at a temperature of 110° F., which was soon raised, however, to 114° F., and she remained in the bath half an hour. During the bath pains began and labor progressed from that time, the head descending characteristically of the generally contracted pelvis, that is, in a position of extreme flexion. A living child was born, there was no atony of the uterus and the puerperium was normal.

Sippel is not led by his few observations to draw general conclusions, but hopes that the profession will give the hot-bath treatment due trial. If it is found that labor can be brought about with tolerable certainty by this method, the induction of premature labor will be freed from its greatest danger, namely, the danger of septic infection.

Dental Memoranda.

COPPER AMALGAM.

BY WILLIAM HERBERT ROLLINS.

THERE are many teeth too decayed to fill with gold, because the operations are too exhausting for the patients and much sound tooth substance must be cut away to make the cavity of the proper shape. The alternatives are gutta percha, cements and amalgams. All the gutta perchas are soft, all the cements are soluble, so that both these kinds of fillings require constant attention.

Amalgams are said to injure the health of patients; to shrink, making leaky fillings; to assume a somewhat globular form in setting, thus drawing out of the angles and allowing moisture to get in; to bulge after setting, through some slow molecular rearrangement, in this way leaking or splitting the tooth; to break at the edges of the filling so allowing food to lodge and produce fresh decay, and also all amalgam fillings change in color.

My experience with amalgam is extensive only with one made of copper. To what extent do these objections apply to this amalgam?

First, I have not yet seen any constitutional effect from its extensive use. Second, with regard to shrinkage—this amalgam does not shrink nor expand. Third, tendency to assume a globular form in hardening. If an irregular hole with sharp angles is made in a plate of glass and the hole packed with copper amalgam and placed in a colored solution, no leakage is seen, so that in this amalgam the globular tendency is not injurious. Fourth, bulging. In several hundred fillings I have seen no case. Fifth, fracture at the edges. Copper amalgam is twice as strong as the ordinary compound amalgams, and although it has not the edge strength of gold, a case has recently been reported in which the fillings on the grinding surfaces of the molars were perfect after twenty years wear. Lastly, copper amalgam does discolor badly: it makes the blackest kind of filling, but does not discolor the tooth unless the filling leaks, when it should be renewed.

Several methods of making this amalgam are given in works on chemistry and dentistry, though they differ in details they all agree in trying to make mercury unite with copper precipitated from a solution of one of its salts. This is difficult in practice, and the amalgam produced by any of these processes is always impure.

The following process is supposed to be new, is simple, and the product pure.

Distilled water 5 gallons. Sulphate of copper C.P. enough to saturate. Sulphuric acid C.P. one pound: mix, filter and pour into a wooden firkin. Place ten pounds of pure mercury in a gallon glass battery-jar and immerse in the copper solution. To the zinc plate of a galvanic-battery attach an insulated copper wire, leaving one end bare for quarter of an inch. This exposed end is then plunged under the surface of the mercury. Tie two pounds of pure granulated copper in a coarse cloth and hang it in the copper solution in the firkin, connecting it by a wire to the carbon of the battery. The battery is to be kept in action till the mercury is a paste.

This paste is to be washed in water and the surplus mercury squeezed through buckskin. The resulting soft amalgam is allowed to harden. On a large scale a dynamo would be more convenient, but one gallon-cell of a Bunsen battery will produce two pounds of amalgam in three days.

PREVENTIVE FILLINGS.

It is rare to find molar teeth in which the fissures formed in development on the grinding surfaces of the crowns do not decay and form cavities in a few years. These fissures are usually of such shape that a semi-liquid material can be worked into them with fine instruments. As soon as a molar has erupted, an attempt should be made to fill all the fissures on the grinding or other surfaces. The tooth should be made dry with absolute alcohol and warm air, after which copper amalgam is to be worked into all the minute cracks with suitable instruments. Copper amalgam is superior to all other substances for this purpose, because while it can be used in a semi-liquid state, it afterwards gets hard and insoluble. If the teeth on one side are treated in this way before decay begins, and on the other side treated in the ordinary way, that is, if nothing is done till more or less extensive decay has appeared, only a few years will be needed to show that this preventive treatment is of value, particularly in those delicate teeth, the first permanent molars.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.

S. J. MIXTER, M.D., SECRETARY.

FEBRUARY 4th 1885. DR. C. B. PORTER presiding. DR. ROYAL WHITMAN reported

A CASE OF PISTOL-SHOT WOUND OF TEMPORAL BONE, FOLLOWED BY ABSCESS OF BRAIN.— AUTOPSY AND SPECIMEN.[1]

DR. GANNETT spoke of a case of cerebral abscess

[1] See page 170.

occurring at the City Hospital, which was remarkable on account of the absence of symptoms that would point to such a lesion. The patient was cook on an English steamer, and twenty-four hours before the time of sailing, having been in the hospital for a short time with slight symptoms, was up and about the ward, and wished to sail the next day. That night he died suddenly. On autopsy an abscess as large as a lemon was found in the right frontal lobe.

DR. E. H. BRADFORD reported

A CASE OF OPERATION FOR THE CURE OF A SPINAL BIFIDA, AND AN OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA,[2]

the two cases being reported together on account of the similarity of the operative procedure.

DR. A. T. CABOT asked the reader if he would inject iodine if the opening into the spinal canal was a large one.

DR. BRADFORD replied that he probably would not, as what was wanted was to set up a slight irritation of the lining of the sac without its extending to the cord. If the sac could be drawn out so as to be clamped at its base, the injection might perhaps be made. He did not know of any cures by this latter method.

In reply to Dr. Harrington, Dr. Bradford said that the advantage in the method of operating adopted by him, was that two layers covered the opening into the spinal canal.

DR. CABOT said that it seemed to him while watching Dr. Bradford's operation, that if a clamp were used to secure the pedicle, the ligature could then be passed and secured without danger.

In remarks on the hernia operation Dr. Green wished to know how many cases of the radical operation resulted in a permanent cure. From his own observations he concludes that all operations that depend for their success on a closure of the ring by a plug of deposited lymph, almost always fail, owing to absorption of the mass, and descent of the hernia. This operation being on a different plan, seems to promise better results. In regard to the success of Heaton's operation, he could say that in the past few months he had seen at least ten cases of relapse, some of which had been reported as successful operations.

DR. BRADFORD said that at the City Hospital many cases had been operated upon by Heaton's method but the cases were seldom followed up so that the final result could be known. In one case, there was now, after two years, no relapse — two operations having been performed. Sometimes the patient can wear a truss after the operation where it was impossible before.

DR. MIXTER spoke of the difficulty in determining the exact point where the oak bark was injected. In several dissections made on children, after injections of colored fluid about the ring by one of the hospital surgeons, the point of the needle was shown to be sometimes in the peritoneal cavity, and sometimes at different points in the vicinity of the ring, rarely in the right spot.

DR. CABOT mentioned a case operated on by him about a year ago for strangulated hernia, where the pillars of the ring were sewed together with catgut, and there was now no return of the hernia.

DR. CONANT spoke of a similar case, operated upon in similar manner, by Dr. J. C. Warren at the Massachusetts General Hospital, and said there had been no relapse.

DR. C. B. PORTER reported

A CASE OF SUPPOSED MULTIPLE SPINA BIFIDA, WHICH PROVED BY MICROSCOPIC EXAMINATION TO BE MULTIPLE CONGENITAL CAVERNOUS LYMPHANGIOMA OF THE BACK.[3]

DR. GANNETT showed the tumors removed by Dr. Porter, together with sections of the same under the microscope.

MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY.

JANUARY 20th, Monument Hall, Charlestown, Z. B. ADAMS, M. D., President, in the chair.

IRREDUCIBLE AND STRANGULATED HERNIA.

DR. S. E. WYMAN, of Cambridge, read an able paper, giving a *résumé* of the descriptive anatomy of the subject. DR. W. EVERETT SMITH, of Framingham, followed with an account of the pathology:

Birkett attributes the strangulation of hernia to a predisposing cause, relying, first, on a previously existing disordered or relaxed state of the bowels, and, second, on a condition of congestion and hypersecretion of the small intestines.

Erichsen, on the contrary, believes these conditions to be the *result* and not the cause.

Three states are recognized: first, simple congestion with effusion of clear serum; extravasation of blood, occurring either from the firmness of the constriction or from the employment of taxis. Second, inflammation; the bowel appears softened, dull-looking, and leathery or pulpy. Lymph is seen on the peritoneal surface, and adhesions among the adjacent tissues. The serum in the sac becomes turbid, coffee-like, or filled with flocculi of exuded white corpuscles. Third, gangrene, commencing at the seat of firmest constriction — more rapid in direct inguinal, and femoral hernia, because the strangulation is more rigid and linear than in other varieties — may quickly involve the whole of the constricted parts, intestine or omentum. Where the pressure is diffused, ulceration and even perforation at the line of stricture is a more common occurrence. The peritoneal surface of the gut is duller than normal, the color ashy or black, adhesions form, the serum of the sac contains blood and pus, and sometimes a general peritonitis occurs. That the return of the gut into the abdomen is the usual cause of this general peritonitis (as maintained by Hutchinson and Gérard), is an assumption not borne out by the facts.

When, after reduction, the bowel ulcerates, either at the line of stricture or, as is common in femoral hernia, at the centre of the knuckle, an extravasation of fæces may occur. This may be localized by adhesions, and an artificial anus result. Statistics from Guy's Hospital Reports clearly go to show, however, that gangrene of the knuckle of intestine with subsequent artificial anus is far more common in femoral than in inguinal hernia, whereas ulceration at the line of stricture is more common in inguinal hernia and results usually from forcible taxis.

The mucus membrane of the gut is deeply congested, from the very beginning of the strangulation,

[2] See page 169.

[3] See page 169.

the villi becoming swollen, softened, and friable. These lesions are especially pronounced at the afferent end of the loop, which is usually open and distended by fæcal matter or gas. The portion below the strangulated loop is diminished in calibre, and is also the seat inflammatory action. The junction of the loop with this portion is always occluded.

Ulceration or gangrene proceeds from within outwards, that is, from the mucous towards the serous surfaces. The ensuing perforation may be very minute and difficult to find.

If the strangulation be sudden and complete, a slough may form in the space of twenty-four or forty-eight hours. If, however, the process of constriction has been gradual, the tissues become thick and leathery, a condition which adds materially to the difficulty of reduction by taxis, but which serves to show that the tissues are not dead.

Gas may be present in the sac, and give a marked crepitation. Fæcal matter is rarely found in the sac.

Strangulation is most violent in the femoral and the incomplete inguinal varieties, perhaps owing to their being overlooked by reason of smaller size than others. It should also be remembered that an old hernia is more liable to strangulation than a recent one, although in the latter, the symptoms are more dangerous, and likely to be attended with mortification. The relative frequency of seats of strangulation in inguinal hernia is, first, internal ring; second, edge of conjoined tendon; third, occasionally only, at outer ring.

ETIOLOGY. DR. WALTER ELA, CAMBRIDGE.

The best view to take to explain the mechanism of strangulation is that it is due to changes taking place in the protruded parts occasioned by their constriction by the tissues external to them. It may be due to an increased size of the hernia, from the presence of gas and fæces in the irreducible form, or it may come about in this way:

A knuckle of intestine or piece of omentum is suddenly protruded during effort of some kind; this immediately becomes compressed by the sides of the narrow aperture through which it has escaped; the return of its venous blood is consequently interfered with, and swelling and œdema rapidly ensue. If the ring is hard and sharp, the strangulated part may thus be deprived of vitality in a few hours. If otherwise, the congestion may run into inflammation. The return of the protruded parts will be rendered difficult or impossible by swelling, by œdema, and by adhesive inflammatory products.

DIFFERENTIAL DIAGNOSIS. DR. J. T. G. NICHOLS, CAMBRIDGE.

Strangulated hernia is most likely to be confounded with *obstructed* hernia, in which the included intestine is filled with fæcal masses and flatus, or with inflammation of the hernia or its sac, caused oftenest by violent taxis or by an ill-fitting truss. In the first-named affection the symptoms are rarely urgent, and by careful manipulation one can often press a portion of the contents of the hernia back into the intestinal canal. In inflammation of the hernia or sac, most commonly seen in irreducible hernia, the distinction is not always easy. Perhaps the rule which will oftenest guide us aright is this: in strangulated hernia the general symptoms precede and predominate over the local; in inflammatory hernia, the local symptoms precede, and are for a considerable time most marked. It is in these cases, in which the life of the patient turns upon our decision, that the rule applies, "When in doubt, operate."

Inflammation of the testis, arrested in its descent through the inguinal canal, may be mistaken for strangulated hernia. So, also, in inflammation of the lymphatic glands in the inguinal or femoral region, care in examination will seldom fail to clear away all doubt. Besides the ordinary seats of hernia, the trouble may show itself in unusual places, and so be overlooked or mistaken for something else. Among these, hernia into the labia majora and in the perineum, can hardly escape detection; so, also, hernia into the vaginal wall, if attention is directed to it. In these situations, hernia is rarely strangulated.

In obturator hernia the diagnosis is often extremely difficult. In many, indeed in most, cases of this rather rare disease there is no tumor to be seen. The pain in most of the cases recorded is described as being along the inner part of the thigh, inner aspect of the knee, and sometimes along the front of the leg and inner side of the foot. The presence of a tumor in the upper and inner part of the thigh, behind the femoral artery, instead of in front as in femoral hernia, might make the diagnosis possible or even easy. The pain follows the distribution of the obturator nerve and its anastomosis, and would of itself justify an exploration of this rather rare seat of hernia, (the obturator anastomoses with the interior cutaneous branch of the anterior crural and the internal saphenous branch). The pain may sometimes be elicited by rotating the hip outward. In cases of doubt, exploration by the rectum or vagina should not be omitted. In one case this hernia was discovered during an operation for the relief of supposed internal strangulation. Five cases are recorded in which this form of hernia was complicated by other herniæ: in one with double femoral, in three with femoral of the same side, in a fifth with inguinal hernia of the same side.

In fourteen out of twenty-five cases reported by Birkett in Holmes's Surgery, obturator hernia was discovered only after death. In hernia through the ischiatic notch, the tumor may be felt under the gluteus maximus muscle.

Diaphragmatic hernia has no certain diagnostic marks. The easiest way to overlook a thing is not to look for it; and this is the cause of many of the fatal mistakes in strangulated hernia. In any case in which the symptoms of strangulation present themselves, it is the duty of the physician to examine with the utmost care, not only the ordinary but the unusual seats of hernia.

HOW DOES IRREDUCIBLE HERNIA AFFECT LIFE INSURANCE? DR. THOMAS CROZIER, CHARLESTOWN.

In the medical selection of lives for insurance, hernia is not a frequent cause for rejection. Various estimates have been made of the proportion of hernia in the general population, varying from 40 to 83 per 1000. In the New England States, particularly in our cities, it is much more frequently met with than in the Western States. During the late war the examinations made on account of the draft showed the extreme prevalence of this disability in this section. About 6000 men were exempted in Boston alone by this disqualification. There does not appear to have been any very exhaustive attempt to fix the propor-

tion throughout the general community, but various estimates make an average of about 60 per 1000 as the proportion in men. A careful examination of the writer's records of all applicants accepted and rejected during ten years, shows that hernia existed in 25 cases per 1000 examined, almost equally divided between right and left inguinal.

Knowledge of any infirmity which would be a bar to acceptance will deter the applicant, and agents are not anxious to lose time in soliciting doubtful cases; and this perhaps explains the comparative rarity of hernia in applicants for insurance. No medical man would pass as an average risk an applicant afflicted with irreducible hernia of any organ; irreducibility in intestinal hernia making strangulation more probable. If a hernia has been relieved by operation, the fact of its having once existed would be no bar to insurance.

Mortality from strangulation and attendant inflammation is a very small item in the losses. One company of long standing, for a recent loss from peritonitis following obstruction of the appendix caeci, paid an amount which would more than cover all losses from hernia during forty years of its existence. A simple hernia unless very large *would not of itself alone* be a sufficient cause for rejection.

The writer desired to call attention in closing to the valuable contribution to vital statistics now accumulating in the ordinary routine of experience of life insurance companies in Europe and America.

TREATMENT OF STRANGULATED HERNIA. S. W. DRIVER, CAMBRIDGE.

When called to a case of strangulated hernia in early stages, after careful examination, ascertaining as nearly as possible the kind of hernia and contents of sac, if no contra-indications, I have always tried gentle taxis even without ether, and have often reduced the hernia. Failing in this, I put patient in favorable position of relaxation, direct hot fomentations, and leave to return after some hours prepared to operate. Give ether, and always aspirate first, whether contents of sac be fluid or gas, or not determined. Then use firm and gentle taxis. (In two cases of crural hernia over forty-eight hours old, I aspirated and reduced; another crural was aspirated, taxis failed, was then relieved by cutting; one large inguinal, aspirated, taxis failed, and was returned after cutting.) Taxis failing, operate. If of a good many hours standing and there are signs of the later pathological changes about the tumor, I should not dare to use taxis, but cut at once.

Epigastric Hernia. I have seen but one epigastric hernia, and that traumatic. Man, aged forty, fell upon a cart-stake. Vomiting, shock, pain, present. Gave ether at once and reduced the hernia which was small and elastic, midway between umbilicus and ensiform cartilage, right. All went well for twenty-four hours, when symptoms of peritonitis appeared and death in six days. If unable to reduce I should have operated at once with similar methods as in any laparotomy.

Umbilical Hernia. One case of non-surgical treatment. Woman, fat, fifty-six, very large hernia, which had been strangulated before and reduced. At this time there was a portion of omentum which had escaped through the lower border of sac into a supplementary pocket. Patient cold, vomiting, colic pains, and bowels becoming tender. Hot fomentations, ether and taxis failed. Gave full doses of opium by injections and stimulants; applied belly-band and hot compresses. After three weeks of very critical symptoms she slowly began to convalesce and was fitted with a large shield truss. Four years after was again attacked with symptoms of obstruction and inflammation; as the contents of the sac could be displaced into the abdominal cavity and no strangulation could be shown to exist, patient was put on same treatment as before, and she died in less than a week. No autopsy.

Other means failing in this form of hernia we must decide whether to operate excising sac and ring under antiseptic precautions, closing the wound as in ovariotomy; or operate less radically freshening edges of ring and bringing together with catgut sutures. I prefer an operation which shall be essentially subcutaneous in those cases where you can locate the edge of the ring and define the sac and contents. (Remember there is no peritoneum covering the hernia.) Two subcutaneous knives, probe-pointed, right and left, with very short cutting edges bent at an angle of 45°, one inch from probe point; also right and left probe-pointed guards, to hold back the neck of the hernia from the ring and guide the knife. Puncture the skin one-half inch from edge of the sac, at point where you can best reach the edge of the ring. Enter probe-guard in front of the ring and press back the sac, following with knife with its back to the hernia and guard; elevate the wrist and nick slightly. I believe I have seen two cases suitable for this method of treatment. Any adhesions might prevent the return of the hernia, but strangulation would be relieved in this way.

I reduced a strangulated umbilical hernia lately, as follows:[1] The patient was fat, fifty years old or more, with a big belly. Hernia size of half a turkey's egg. Failing with ordinary taxis, I gathered the tumor together with all the fingers and thumbs of both hands and while exercising firm pressure lifted the anterior abdominal wall with careful force, hoping that either the shortness of the mesenteric attachments or spasmodic contraction would act as counter extension; at the same time I vibrated my hands with a view as it were to *unbutton* the ring. I was gratified to find that there was a counter-extension force and felt the hernia slipping through and dropping out of sight and touch. This hernia had been strangulated for twelve hours.

Oblique Inguinal Hernia. Here Dr. Driver explained in detail his method of operating. It is not desirable to open the sac if you can avoid it. The pons asinorum is to determine when you are in the sac. In case of small hernia with thick indurated sac there may be difficulty. Ordinarily you can pick up and divide each layer separately. The moment you slit the peritoneal layer there is a flow of liquid of greater or less amount. To release the strangulation a very slight nick ordinarily suffices. Slight adhesions in the contents of sac may be separated, but if extensive and the history is that of an old hernia long down, you will have to be satisfied with releasing the strangulation. If the sac contents, whether omentum or intestine, be necrosed you must generally leave it and drain the wound. In some cases necrosed portions of omentum had better be cut away and cat-gut ligatures applied to bleeding vessels.

Direct Inguinal Hernia. This requires similar treatment to the last mentioned, and great care should be exercised in picking up the layers external to the sac,

[1] This method I have not seen described in any book of surgery nor by any surgeon.—S. W. D.

remembering always that the internal epigastric artery lies external to the sac.

Crural Hernia. Do not mistake for omentum a layer of fat lying beneath the fascia propria. "Feel for obturator artery before cutting."

Obturator Hernia. This is rare. The incision is begun above Poupart's ligament at a point midway between spine of pubes and artery, exposing fascia covering pectineus muscle. Divide its fascia and separate the fibres of this muscle. Then dividing fat and separating fibres of the obturator muscle you can place your finger on the outlet of the obturator canal. Other rules apply as in the treatment of hernia above explained.

CASES OF STRANGULATED HERNIA.

July 2, 1874, M. D., age eighty. Large scrotal hernia, left. Seen at night, symptoms indicated strangulation. Ordered opium and hot compresses. Consultation in morning with Drs. Nichols and Wyman. Ether, aspiration and taxis failed to reduce. Cut down upon neck of sac with T incision. Dilated ring with the fingers. Failed to reduce and opened the sac. Nicked upper border of ring with hernia knife and reduced easily. Wound dressed antiseptically. All went well for four days. Wound closed kindly without tenderness or redness. Patient had a chill followed by swelling of left parotid gland, followed soon by inflammation and imperfect suppuration. This was opened but patient sank and died on the seventh day with symptoms of blood-poisoning. This occurrence may be cited to show the sympathy between the testis and parotid gland, as in mumps.

Mrs. H., American, age seventy. Right crural hernia. Symptoms of strangulation for two days. Directed hot applications, left her and returned after a short interval prepared to operate. Gave ether and aspirated a small amount of dirty fluid. Then, after a careful and not severe taxis reduced the hernia. Patient sank in twenty-four hours. Treatment, stimulants and opium. I think in this case, not alone because the patient was old, but because of weakness of age, delay was fatal.

Dr. Driver showed specimen of a hard thickened hernial sac, crural, and a section of the large intestine in which was a segment of dark brown tissue marking the point where one-third of the lumen of the tube had been caught in the sac; there had been no necrosis of tissue but only intense congestion.

History. English woman; good circumstances, age eighty-two. Subject for many years, in August and September, to attacks of vomiting and later diarrhœa, caused generally by eating fruit or vegetables. On Sunday she ate peaches, on Monday complained of pain, nausea and vomiting. Wednesday vomiting recurred during night and at noon was reported to be stercoraceous. I had known patient for many years, had attended her in many similar attacks, but had never had any report of a tumor or swelling in her groin or anywhere else. On the appearance of this new symptom I examined for hernia and found this tumor in left groin. In consultation next morning Dr. Wyman aspirated a few drops of fluid and then reduced by taxis. Patient sank during following night. Autopsy showed no peritonitis even commencing. Patient died from shock.

These cases teach us the danger of delay in the aged. Where had this hernia been? what its history during all the years of its unrecognized existence?

Symptoms of patient and condition of tumor, not the age of the patient, should be the factors to decide the problem of procedure. In the earlier hours, gentle taxis without ether will sometimes succeed. Failing in this, and always when the case is seen late, the order is, ether, then aspiration, gentle firm taxis, and these failing, cut.

Dr. E. R. Cutler, of Waltham, cited cases, stating that he had operated ten times for strangulation. That the operation presented no difficulties, and if not delayed too late, or if no violent taxis had been employed, was, generally speaking, successful. That the danger was in delay and temporizing measures.

The President, Dr. Adams, in concluding the discussion of the subject, stated that he had lately had the pleasure to hear a paper read before the New York State Medical Association, at its annual meeting in New York, entitled, "The Difference in the Symptoms of Strangulated Oblique Inguinal Hernia," by Dr. Hyde, of Courtland County, New York, and also the question further discussed in a paper by Dr. John W. S. Gouley, of New York. The following is a summary of what was then heard, with one or two observations and illustrations derived from the writer's experience.

Repeated forcible attempts at taxis are dangerous and tend to enhance the risks of the operation which must be afterwards made, by increasing the inflammation and œdema of the parts. Dr. Gouley said that two minutes' trial in a warm bath is all that should be permitted.

By violent taxis doubtless a reduction may be produced *en bloc*, but this is believed to be a rare occurrence. Much more frequently may taxis deceive by causing a disappearance of the contents of the sac or of the fæcal matter in the intestine, while the hernia still remains unreduced and as much a source of danger as ever. An œdema caused by the taxis may also obscure and cover up the true condition of the parts.

The danger from opium is two-fold: first, we may be lulled into a false security and thus be led to defer operation until sphacelation has occurred, an accident especially liable to happen in the aged and in the case of a small omental hernia. Second, opium may cause such a degree of dryness of secretion, accompanied with constipation, vomiting, etc., and such nervous phenomena, as to lead us to think an operation called for when in fact the symptoms are chiefly due to the remedy. This especially in old irreducible cases. And in this connexion the fact should be noted that the doses of opium recommended in strangulation are poisonously large.

When once the diagnosis of strangulated hernia is made, there should be no delay in operating.

Dr. Gouley cited two cases where an operation for hernia was done, no hernia existing; enlarged glands were found and removed, and no harm done.

The age of the hernial strangulation is a very important factor, the age of the patient very much less so.

Successful cases of operation, it is true, are reported after six days, and even it is claimed thirteen days, of strangulation.

It is certain also that old herniæ, of long standing, will endure pretty severe taxis without grave injury resulting.

Symptoms, even in fatal cases, may be almost entirely absent. There may be neither tumor nor pain nor peritonitis nor vomiting.

Of this sort was my first case of strangulated hernia, thirty years ago. Feeble man, eighty years old, a dispensary patient. There were absolutely no symptoms except prostration, constipation and occasional but rare vomiting. On the second day a careful inspection disclosed a slight blush in one of the groins, but no tumor. Dr. R. M. Hodges, who kindly saw the man with me, thought it might be well to explore by cutting. A bit of strangulated omentum not larger than a small pea was found sphacelated. The man died soon after.

In general, it may be said that the symptoms, local and general, are less severe in inguinal, (especially oblique), than in femoral hernia, and that there is less danger in operating.

In the summer of 1882, Mrs. E., wife of a well-to-do farmer, age about fifty years, and of rather delicate constitution, was attacked somewhat suddenly with symptoms of strangulation. On examination an irreducible inguinal hernia of the left side, about as large as half a hen's egg was disclosed, which had existed for years, had never given her any trouble, and for which she had never used a truss. It was slightly tender, there was colic pain, with tympanites, obstinate constipation, vomiting, etc. She was treated with opium, rest, turpentine stupes and injections; and at the end of a week, without resorting to taxis or any other means, recovered.

In the summer of the next year she had another attack with the same or similar symptoms. In this second sickness there was no œdema, swelling, nor tenderness in the region of the tumor, and scarcely any pain. Feeling great confidence that the same happy result would follow from the use of opium as in the former seizure, the same treatment was ordered again. Her condition becoming alarming, she was seen by another physician in my absence. An operation was advised and practised, and a condition of gangrene disclosed. She sank a few hours after.

NEW YORK ACADEMY OF MEDICINE.

STATED meeting, February 3d, 1886.

DR. M. A. STARR read a somewhat technical paper on

THE INTRA-CEREBRAL TRACTS, THEIR PHYSIOLOGY AND ITS BEARING ON THE DIAGNOSIS OF LESIONS OF THE CENTRUM SEMI-OVALE,

which was illustrated by different specimens of brains prepared in such a way as to exhibit the three sets of fibres, the projection, the commissural, and the association fibres.

DR. A. G. CAILLE read a paper on

PERMANENT DRAINAGE IN ASCITES.

He began by relating the case of an elderly gentleman who applied to him for treatment about four years ago, suffering from cirrhosis of the liver. This soon necessitated tapping and in the course of the next seven months he was tapped no less than nine times. Before resorting to a tenth tapping Dr. Caille determined that he would make a fistula in the abdominal walls, and put in a permanent drainage-tube. He therefore made an incision one inch in length in the linea alba below the umbilicus, and inserted an inch of drainage-tube into the peritoneal sac; retaining it by means of a varnished safety-pin, and using antiseptic precautions in the dressings applied. In about a week an eczema of the abdomen and thighs developed, owing to the fact that the patient could not keep himself dry by means of the cloths with which he was supplied. The abdomen and thighs were then smeared with mutton tallow, and the eczema disappeared in six days.

The result of the permanent drainage was, that the general œdema and all the other distressing symptoms from which the patient had been suffering, disappeared. He was soon able to go about with ease, and for nine months was able to attend to his ordinary avocations, contented and comfortable. He finally died from heart failure. When the drainage-tube was first put in from two to three pints of fluid were excreted daily; but this gradually diminished, until it ceased entirely, and the ascites never reäppeared. An autopsy was made; when it was found that there was cirrhosis of the liver, with cardiac hypertrophy. There was not the slightest evidence of peritonitis at the point where the tube had been inserted.

A second case was that of a man forty-six years of age, who had been a confirmed whiskey drinker, and who was suffering from cirrhosis of the liver, ascites and general anasarca, with all the distressing symptoms usually attending such a condition. He also had purpura hæmorrhagica, stomatitis and vomiting, and the heart's action was irregular and miserable. He was tapped once, and then the fluid reäccumulating, Dr. Caille made an opening, and inserted a drainage-tube in the same manner as in the preceding case; protecting the parts with iodoform gauze and dry towels. When the patient was in bed or sitting in a chair, a rubber tube conveying the fluid to a vessel on the floor was often attached to the drainage-tube. There was at once great improvement in the general condition; but about three weeks after the fistula was made, the patient suffered from a severe attack of epistaxis, which necessitated the plugging of the posterior nares. The purpura, vomiting, stomatitis and other troubles then disappeared, and he lived in comfort, without any return of the ascites, for a considerable period; finally dying of paralysis of the heart. In this case no autopsy was made.

Of course, he said, it was not claimed that this treatment was curative. Its object was simply the amelioration of the troublesome symptoms always associated with ascites. All the points involved in it were comprehended in a discussion of four questions. The first was, what are the symptoms most troublesome and dangerous in ascites? Ascites might occur alone, or associated with general anasarca; but in either case, dyspnœa, flatulence, constipation, debility, renal trouble from the pressure of the fluid, and a host of other troubles were liable to ensue.

The second question was, how is collateral circulation established in cirrhosis of the liver? At some length, Dr. Caille pointed out the various channels through which this might be accomplished.

The third question was, will absence of intra-abdominal pressure promote collateral circulation, the functional activity of other organs, and the comfort of the patient; as well as tend to prolong life? This he answered in the affirmative.

The fourth question was, how is drainage best accomplished? It could not be denied, he said, that the large amount of fluid which was drawn from the sys-

tem by the method which he advocated, constituted a considerable drain upon the vital forces, and he showed what an amount of albumen would thus be abstracted in a given time; but, on the other hand, this was of comparatively little importance on account of the benefit derived from the better performance of the functions of other organs which resulted from the establishment of drainage.

He then went on to say that the *technique* of the proposed plan of procedure might be improved upon. For instance, a hard rubber or glass tube might be employed and a flat bag or antiseptic pad, to be worn on the abdomen below the fistula, might be provided. In all cases it was necessary that antiseptic precautions should be observed; though the danger from penetrating the peritoneum was found to be much less when ascites was present than under other circumstances. A large experience, he said in conclusion, was needed to determine the indications for permanent drainage, and the cases in which it was applicable.

The President, DR. A. JACOBI, said that the procedure described in the paper was an imitation of what is sometimes accomplished by nature spontaneously. Spontaneous rupture of the abdominal walls might take place in ascites, and it was not an infrequent occurrence. It sometimes took place in the linea alba, but most commonly at the umbilicus. The fistula made by nature, however, might be in a spot that was inconvenient or uncomfortable for the patient; but when the surgeon made an artificial fistula he could select the place which would be in every way most satisfactory. Not long since he had seen in the German Hospital a patient in whose case a spontaneous fistula had been already established when he came under observation. While he remained in the hospital he lost fifty pounds in weight, and he went out feeling comfortable and able to work.

He then related another case in which he said he had to resort to permanent drainage. This patient was a young woman, twenty-three years of age, in his service at Bellevue Hospital, who had a history of anæmia and chlorosis; having been nineteen before she began to menstruate. For six or seven months before admission menstruation had ceased, and some six months before the cessation she had noticed a circumscribed swelling in the right hypogastric region. This gradually increased in size until she came into the hospital, when it was found that the tumor was quite large. At that time, however, it was two-thirds in the left hypogastric region, and only one-third in the right. There was decided tympanitis in the renal region and over the ascending colon. From the fluctuation recognized through the tumor he decided that it was a cyst, and probably an ovarian cyst, originating in the right ovary. The uterus was normal.

An abdominal incision was made with a view of removing the tumor; when it was found that there was no cyst at all. The condition present was, in fact, ascites, with abundant adhesions on both sides; and a glass tube was left in the abdominal opening for six weeks. In the meanwhile, the fluid did not return, and the patient was discharged in an improved condition. Afterwards, however, he learned that there had been no reäccumulation. In this instance the ascites was probably due to tubercular peritonitis, and the fatal termination was only a matter of time. Dr. Jacobi remarked that a number of years ago he had made precisely the same mistake in diagnosis; but it was one to which all were liable, since ascites when thus circumscribed by adhesions presented exactly the same characteristics as an ovarian cyst.

A third case which he related had come under observation after he had become acquainted with Dr. Caille's method of procedure. The patient had cirrhosis of the liver, and suffered from icterus, purpura, epistaxis, dyspnœa and loss of strength. He introduced a trocar through the abdominal walls midway between the umbilicus and bladder, and through this inserted a sterilized tube into the peritoneal cavity. To this was attached a rubber tube to convey the fluid to a pail under the bed. This procedure was adopted as a palliative measure to give the patient, who was in a hopeless condition, as much comfort as possible, and the tube was kept in position until he died. At night it was usually plugged up with wax. The quantity of fluid which flowed through it at first was extremely large, but gradually became smaller and smaller. The general condition of the patient after the operation was favorable; but he finally died from exhaustion. At the autopsy there was not the slightest evidence of local peritonitis found. Dr. Jacobi said, in conclusion, that he was convinced that the plan proposed was a good one, and that he should repeat the operation whenever suitable cases presented themselves.

DR. LINDLEY inquired whether any medicinal treatment for the relief of the condition was used in Dr. Caille's cases, in addition to the establishment of permanent drainage.

DR. MEYER stated that he had had under his charge a case of cellulitis ending in a large accumulation of pus, in which a fistula was spontaneously formed below the umbilicus. In this instance he made a counter-opening from the peritoneal cavity into the vagina, and through this the pus had been discharging for the last two years. The quantity had, however, been gradually diminishing, and the cellulitis was also decreasing. In ascites also, occurring in females, it had occurred to him, therefore, that it might be advisable to make an opening into the vagina.

In reply to a question from the chair whether in the case mentioned, he was sure that the pus was in the abdominal cavity, Dr. Meyer said that he was positive of this, and that the patient had previously had peritonitis.

Dr. Caille having stated that in his cases great care was used in the selection of food, but that no medicine had been used with the exception of Horsford's Acid Phosphate, Dr. Lindley said that among the Dutch in South Africa he had found that honey was held in very high repute in cases of abdominal dropsy. He then related a case of his own there, in which, after tapping, the fluid rapidly reaccumulated. He was then persuaded by some of the old women to try the effect of honey; when to his surprise, the man, although he had every indication of cirrhosis of the liver, began to improve, and in time was apparently entirely cured. He would not pretend to give any explanation of this, but thought that it was worthy of note that the people there had such universal confidence in the efficacy of honey.

DR. B. F. SHERMAN, of Ogdensburg, suggested that the peculiar virtue of the South African honey might perhaps be derived from the flowers from which it was gathered by the bees.

DR. JACOBI then made some remarks on the medicinal treatment of the affection in question. He was

confident, he said, that he had seen cases of cirrhosis of the liver getting perfectly well; but it was to be remembered that an interstitial hepatitis was not necessarily a universal hepatitis, just as interstitial nephritis, myelitis, and encephalitis might be partial, instead of involving the whole extent of the organ affected. In a number of cases which had come under his observation in which the diagnosis of cirrhosis had been made by himself and others, the ascites had disappeared, and now returned; the liver getting smaller, without a corresponding enlargement of the spleen, and the patient becoming practically well.

The treatment was to his mind simple. When he met such cases of interstitial inflammation in practice, and could make out a history of syphilitic trouble, we always congratulated ourselves and the patient on this account, because of the more favorable prognosis which it enabled us to make; there being a fair chance of recovery as a result of an appropriate course of treatment with iodide of potassium and bichloride of mercury. He then remarked that as a student he had been taught that it was a cruel thing to give mercury; that it was antiplastic, and that if with it you succeeded in curing the disease present in any case, it was only to destroy the patient with the remedy employed. Except in syphilitic cases, therefore, for a number of years he used no mercury whatever in his practice. During the last ten or fifteen years, however, he had been endeavoring to make up for this mistake in regard to this really most useful agent. He had found by experience that in various forms of interstitial inflammation, mercury was often very beneficial, and in this connection he related a case of tabes which he had had under his observation for about twenty-five years. For a long time there was no improvement, although nitrate of silver and other agents had been faithfully tried; but since he had resorted to the use of mercury there had been marked progress, and the patient, although he had never had syphilis, was now practically well.

In interstitial hepatitis, nephritis, myelitis, and encephalitis, therefore, he would recommend the use of mercury; and it should be given in such a form and in such doses as could be taken for a long time. As a rule, the bichloride was the most suitable preparation and it might be given, largely diluted, in solution, or preferably in pills; the ordinary amount called for being about one-tenth of a grain three times a day. The patient should be instructed to use a chlorate of potash wash and to carefully watch his gums. The cyanide of mercury had been recommended by some; but he had had little experience with it.

NEW YORK NEUROLOGICAL SOCIETY.

STATED Meeting January 4, 1886. The President, W. R. BIRDSALL, M.D., in the chair.

A CASE OF SOFTENING OF THE CORPORA STRIATA, WITH SPECIMEN.

DR. J. C SHAW related the case, that of a gentleman thirty-eight years of age, whom he saw for the first time in July, 1883, in consultation with Dr. Fuller. The patient was a large man, healthy in appearance. About a month previously he had an attack of hemiplegia on the right side, with very temporary loss of consciousness. When Dr. Shaw saw him the arm had entirely recovered, but there was still dragging of the leg. The tendon reflex of that side was exaggerated. There had been no premonitory symptoms except that for six months previous the patient had at times been exceedingly irritable. He denied having had headache, or syphilis, and claimed that if it were not for the paralysis of the leg he would be in perfect health. At this time Dr. Shaw was in some doubt regarding the nature of the lesion; the diagnosis seemed to lie between cerebral hæmorrhage and a possible meningo-encephalitis. Against cerebral hæmorrhage was his age and the dragging of the foot, the toe scraping the floor; and about the only point which favored meningo-encephalitis was mental irritability. The patient would take no medicine except cathartics.

Dr. Shaw saw him again in consultation in June, 1884. He had suddenly become completely hemiplegic upon the left side; was unconscious and had stertorous respiration; he passed his urine and fæces in bed. Recovery gradually took place from this unconscious state. Paralysis remained on the left side. Trophic troubles began in the joints of the paralyzed arm, accompanied with pain. Patient would cry when spoken to, and could give no history of himself. At this attack Dr. Shaw concluded that there was cerebral arteritis, probably syphilitic, and thrombosis. The patient accused his wife of infidelity, became very noisy at night, and was sent to an institution, where he died in October, 1884.

At the autopsy the viscera appeared to the naked eye to be normal. Nothing special was observed in the meninges. Then ventricles were distended with fluid, and contained granulations. The corpora straita were softened, due to arteritis of both middle cerebral arteries and their branches. There was secondary degeneration in the cord on both sides, and the case seemed to illustrate the unequalness of the decussating fibres on the two sides. The degeneration on the right side in this instance being much more marked than on the left.

Dr. Shaw said that the points of interest to him were, that both arteries should have been involved in the arteritis, causing softening of the corpora straita on both sides. That the patient saw dogs, etc., at night, which might have been a form of visual hallucination. Lastly, the accusation of his wife of unfaithfulness, a symptom which is frequently met in chronic alcoholics, but rarely in other conditions.

DR. E. C. SEGUIN asked if there was not probably involvement of at least one internal capsule.

DR. SHAW replied that there was, and that the case probably was not one of limited involvement of the corpora striata.

DR. SEGUIN thought a point of interest was the fact that granulations were found in the ventricles, for this was a rare pathological condition except in general paralysis. It was sometimes found in other conditions, as chronic mania.

DR. SHAW said the granulations in this case were marked. He had seen granulations on the floor of the ventricles in a variety of conditions, in the chronic insane and others. Sections of the cerebral cortex did not show the lesions characteristic of general paralysis. Dr. Seguin may have noticed that the patient was unusually satisfied with his condition, almost amounting to delirium of satisfaction.

DR. GRACE PECKHAM then read a paper entitled,

MIRROR WRITING AND OTHER PATHOLOGICAL CHIROGRAPHY OF NERVOUS ORIGIN.

The paper was introduced by a reference to the expression of individuality in handwriting. "As the members of the body are the servants of the brain to carry out its will in motion, as the vocal organs express its thoughts in sounds, so in the act of writing the hand embodies the subtleties of cerebral action; it is therefore in writing that we may find express deviations from normal nervous conditions, sometimes too slight to be indicated in any other way."

The physiology of the handwriting was next considered. Poore's views with regard to the muscles employed in the act of writing were quoted. At no time in the act of writing are fewer than two nerves engaged. The cerebral centres which preside over writing and the inter-commissural tracts are not fully made out. Charcot and others think there is a word motor representative centre situated at the base of the left third frontal convolution, near Broca's centre of speech; auditory centres, employed when writing to dictation, in the temoral convolution; ocular centres, used when copying, in the parietal convolution.

We have a right-handed writing to be written with a centrifugal motion, in one direction, across the page from left to right, a writing which taxes the weak muscles of the hands, and which takes four or five times as long as is necessary for the representation of a word as is shown by stenographers who write as fast as a person can speak. In view of the increase of writer's cramp due to the extraordinary amount of writing to be done by book-keepers, book-writers, teachers and savants, it was suggested that a new method of writing should be intelligently discussed and one inaugurated which should be less elaborate, less taxing upon the small and weak muscles of the hand; a handwriting in which the letters can be formed as in the phonograph, disconnected, not requiring such precise and complicated motion to make them legible, and which can be written from above downward, from right to left or left to right, as one may choose.

Bianchi, in Italy, and Erlenmeyer, in Germany, were almost the only ones who had entered into the study of the pathological signification of the handwriting. The subject had been considered in a disconnected way as a symptom of some diseases treated of in various text-books. However remotely alluded to, there had been a general acknowledgment of the value of a diagnostic sign of the handwriting of disease.

The handwriting may become pathological through the alteration of any portion of the mechanism involved in its production. The paper included only a discussion of the changes produced by abnormal conditions of the nervous apparatus. Alterations in the handwriting may be mechanical or psychical, ataxic or tremulous, or a mingling of the two forms. The ataxic is physiological when seen in childhood, before the power of co-ordination of muscles for the complex act has been acquired. The tremor is physiological in the handwriting of the aged, in which also is seen a tendency to retrograde into childish handwriting. The principal pathological handwritings are: —

(1) Handwriting resulting from trauma to the nerves. (2) Mirror writing and agraphia, caused by injury to the cerebral centres. (3) Handwriting of general paralysis, caused by alteration of cerebral tissue. (4) Handwriting caused by sclerosis, cerebral and spinal. (5) Handwriting caused by functional disturbance, including paralysis agitans and writer's cramp.

Samples of handwriting can be shown occasioned by the interference with the conducting nerve-fibres. Erlenmeyer exhibits a very curious specimen in which there was injury to the radial nerve. The tremulousness, or, rather, interruption of the lines, especially of the upper stroke, is very peculiar.

It is to be regretted that handwriting following injury to nerves has not been more studied, as much of interest from a physiological as well as a pathological point of view might be attained.

At present, considerable discussion has been awakened with reference to mirror writing. Ireland called especial attention to it by his paper in *Brain*, in 1883. Hughlings, Jackson and Buchwald, first discovered mirror writing. From experimentation and investigation of the subject the writer reached the following conclusions: —

First. That mirror-writing may indicate a change in the perception of the nerve-centres of the brain, what Erlenmeyer would call retrographia. The patient suffering from this would read the reversed writing certainly as easily as the normal. This would be a means of diagnosis between a cerebral mirror-writing and one from mechanical causes alone.

Second. That from twenty-five careful examinations of cases on record no indication has been found that the mirror-writing occurred from other cause than a mechanical one; that is, the person writing with the left hand could do so more easily in a centrifugal than in a centripetal direction, the former association of ideas and muscular action making this so. Therefore a person weakened by disease, weak-minded children, and left-handed persons, would write centrifugally, or mirror-writing. The reason lies, therefore, not in a pathological, but in a physiological condition.

The subject of agraphia has been much discussed of late with that of aphasia. It was first spoken of by Marce, in 1856. There are very few cases of agraphia uncomplicated with aphasia on record. In agraphia, there may be word blindness, word deafness, or a volitional motor disturbance resulting in inability to write. The investigators of the subject have entered deeply into the discussion of the seat of the writing centre in the left hemisphere. The unilateral theory is not so fully endorsed as hitherto.

The diagnostic value of the handwriting in agraphia resides in the evidence it gives of the extent of damage done to the brain tissue in these cases of hemiplegia, and also an indication of the location of the trouble.

In the early stages the handwriting of the insane indicates little the invasion of the disease, but when there is bad spelling and omission of words it should awaken suspicion. The progress of the malady is marked by changes in the handwriting. It is the reverse of that of childhood. In the first stage there is a diminution of the handwriting, a running of the words together, and either not finishing the final letter or terminating it in an irregular outline or dropping it entirely. The letters are shaky, irregular, and there is a plentiful besprinkling of capitals. Later the letters are coarse, irregular, in uneven lines, and finally there are scattered pot-hooks and ataxic marks, like a child first learning to write.

The handwriting of multiple cerebro-spinal sclerosis is characterized by tremulousness.

In locomotor ataxia involving the upper extremities

the changes are shown early when writing with the eyes closed, especially in round letters and l and e. They are formed by straight lines, more or less extended, instead of curves. When the disease is further advanced the writing is ataxic when the eyes are open, though not so much so as when they are closed. Later there is inability to write a single word.

The functional disturbances of the handwriting include the handwriting of paralysis agitans and writer's cramp, as also that of chorea and hysteria. In the two latter there is nothing of special diagnostic value. The writing of paralysis agitans shows the tremor in the early stages. Even when the handwriting looks normal to the naked eye, a glass will reveal the peculiar character given it by trembling. In writer's cramp the writing shows many forms of disturbance, and were there no history it would be difficult to say whether we were dealing with some of the various forms of tremor, paralysis agitans, progressive muscular atrophy, etc. A study of the handwriting will, however, reveal the nature of the disturbance, whether it is of the spastic, tremulous, or paralytic form.

DISCUSSION ON DR. PECKHAM'S PAPER.

DR. E. C. SEGUIN said that in his practice he had frequently derived considerable help in diagnosis from the patient's handwriting. He thought the medico-legal aspect of pathological handwriting might after further study assume considerable importance. It would be of value to be able to say in a court of law whether a given specimen of handwriting were that of an aged imbecile, a general paralytic, or an intoxicated person.

DR. LESZYNSKY thought he could hardly say from the specimens of handwriting of paralysis agitans presented that they were characteristic of that disease. He had a number of specimens of handwriting of chronic alcoholismus which were almost exactly similar. Dr. Peckham had not mentioned the handwriting of epileptics, nor had he read of anything characteristic about it, but he could recall two epileptics whose handwriting appeared to be rather unique. In some epileptics there was the condition known as the echo sign, being a repetition of words during conversation. He had seen the same thing manifested in the writing in two cases. He had recently had a case of telegrapher's cramp in which the movements were markedly ataxic, being without any control.

DR. PUTNAM JACOBI had been struck by the great varieties and peculiarities in the handwriting of persons in usual health. Some of the peculiarities supposed to be more or less characteristic of the handwriting of diseased states were also observable in the handwriting of certain persons in a state of health. For instance, Dr. Jacobi was unable without giving special attention to write in a direct line across the page: the line always sloped downward. The question had suggested itself to her whether in the case of the insane the tendency, especially after writing for a while, to slope the line downward and to use capitals profusely, was not due to mental fatigue; and the use of capitals might be due to a desire to emphasize an idea which a fatigued and feeble brain was incapable of correctly expressing.

DR. DANA said he did not think it would be practical for everybody to learn shorthand instead of other writing, but he thought some modification of shorthand might be adopted. There would result perhaps greater facility of expression if present methods of writing were simplified, but there would no doubt be an increased amount of writing which perhaps would be a greater misfortune.

Regarding mirror-writing he thought it was physiological. When we educate the centres to write with the right hand we at the same time educate to some extent the automatic centres for left-hand or mirror-writing. If a person put a pencil in either hand and attempt to write his own name, he will find that the left hand will write mirror-writing while from the right hand the usual writing will result. If then by hæmorrhage the centre for right-hand writing be destroyed it would be perfectly natural for the centre controlling left-hand writing, if not corrected by the will, to produce mirror-writing.

DR. A. B. JUDSON presented a specimen of mirror-writing by a negro girl, eleven years of age, produced ten years ago. She had slight right hemiplegia, but was able to perform household work with the right hand, and she could also write somewhat with it. The writing with the left hand was a fine specimen of mirror-writing.

DR. PECKHAM closed the discussion, and said that the echo sign, the repetition of written words, was well shown in the third specimen presented, that of a woman who had right hemiplegia and amnesic agraphia. Regarding the use of capitals and the tendency to underscore by the insane, she thought it in harmony with their exaggerated ideas.

Recent Literature.

Manuel de Technique des Autopsies. Par BOURNEVILLE et P. BRICON. Avec 16 figures et 5 planches. Paris: Librarie du Progrès Médcal. 1885.

This little book fulfills the purpose which its authors have indicated in its title. It is a concise and excellent guide-book for the performance of autopsies in accordance with scientific methods. It tells us what instruments to use, and how to use them; it describes the order in which the various organs should be examined, and explains the best way of their external and internal inspection.

With each step in the process, it gives a brief mention of the abnormal changes which may be found and which should be sought. In all this, the principal part of their work, the authors have given in new language, and with more or less elaboration in details, that which was already familiar to most students of pathological anatomy in the well-known manual of Virchow. To those who wish a safe and eminently practical guide through the somewhat mazy details of a full autopsy, this book may cordially be commended.

In addition to the purely technical matters relating to a post-mortem examination, the book contains interesting chapters on the bibliography of the subject, on the social and legal usages of various countries relating to autopsies, and on preservative processes and agents. It seems to have escaped the authors' recollection that most geographers make mention of a nation called the United States; it is satisfactory to learn that at Port-au-Prince, in Hayti, autopsies are made soon after death, because the climate promotes early decomposition, but why Port-au-Prince should be distinguished as the only locality on this side of the Atlantic worthy of any mention, is left wholly to the imagination.

Medical and Surgical Journal.

THURSDAY, FEBRUARY 25, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

PTOMAINES AND LEUCOMAINES.

PANUM in 1856 demonstrated that there exists in animal substances undergoing decomposition a poison of extreme activity. Armand Gautier, in 1870 discovered in the muscular juice of healthy animals, and even in their urine, certain alkaloids which he called *leucomaines*. In 1876 Selmi, in searching for arsenic in a cadaver that had been exhumed after thirty days' burial, discovered a toxic and crystallizable principle to which he gave the name *ptomaine*. All these animal alkaloids are similar in their nature to those produced by plants, but are supposed to be either a product of simple chemical decomposition, or a secretion of the animal cell under certain conditions (like vegetal poison) or else the work of bacteria.

These alkaloids are markedly toxic. Gautier's leucomaines have an action on the economy similar to that of strychnia; they more nearly resemble, however, the fly fungus muscarine in their physiological effects; among these are stupor, tetanic convulsions, cardiac irregularities with finally death by tetany of that organ. Brieger has recently found a base by the action of ether on nerve tissue, to which he has given the name of *neuridine;* it is non-toxic, but by simple exposure to air in a watery solution it is converted into that deadly poison muscarine; this same experimenter also claims to have obtained an alkaloid of the nature of ptomaine from the action of gastric juice on fibrin. Tanret, the well-known French pharmacist, has announced that alkaloids are generated by the simple contact of peptones with alkaline salts, while Bouchard and Arnold have completed researches in this direction by showing that toxic alkaloids of the nature of ptomaines may be extracted from fæcal matters.

In a remarkable communication lately presented to the Academy of Medicine, France, by Dr. Gautier, on "The Alkaloids Derived from Bacterial or Physiological Destruction of the Animal Tissues,"[1] are given some facts regarding these ptomaines which are worthy of reproduction in this connection. The ptomaines form salts such as sulphates, hydrochlorates, etc. The free ptomaines have some of them a pungent, some a urinous odor, some smell like hawthorn, some like wild rose, or orange flower. They have for the most part a piquant savor, which benumbs the tongue and is attended with a choking sensation.

Gautier gives the process of obtaining some of the principal animal alkaloids. Putrefying meat is subjected to the action of ether, and certain alkaline principles are dissolved out, which resemble at once sperm and methylamine. The alkaloids are isolated by evaporating off the ether; they are then dissolved in water. A gramme of this solution injected in a dog produces stupefaction, tremblings, chronic spasms of all the muscles of the trunk, slowing of the respiration and death after forty-five minutes. The heart is found arrested in systole.

After exhaustion of the putrefied viscus or muscle by ether, new alkaline bases may be got by subjecting the same parts to the action of chloroform. The solvent being evaporated away the residual ptomaines are taken up by acidulated water. A subcutaneous injection of the latter causes death in the dog with symptoms similar to those produced by veratrin or digitalin. If the residue of the ether and chloroform maceration be exposed to the action of amylic alcohol still a third series of ptomaines is extracted, which, injected in frogs, cause general anæsthesia and prostration and death after a few minutes. These ptomaines were obtained by Dr. Gautier from a human cadaver exhumed after being buried ninety-six days.

These are some of Gautier's conclusions:

(1) The fixed cadaveric alkaloids or ptomaines are venomous to a high degree.

(2) The free ptomaines are more poisonous than their salts, and those are especially toxic that are soluble in ether.

The principle phenomena to which they give rise in the frog are the following: (1) Dilatation, followed by contraction of the pupil. (2) Tetanic convulsions, followed by muscular flaccidity. (3) Slowing of the heart. (4) Absolute cutaneous anæsthesia. (5) Loss of muscular contractility.

In the dog similar phenomena are observed; death is preceded by somnolence and convulsions. These symptoms resemble those produced by muscarine.

Gautier, in some of his experiments, found a nitrogenous base, with formula $C^8 H^{11} N$, which he named *hydrocollidine*, the symptoms following the injection of which in birds and small animals resemble those of the venom of the most poisonous serpents, the cobra di capello, for instance. One milligramme kills a sparrow in an hour, with general spasmodic agitation and paralysis.

Continuing his investigations, the author of the memoir from which we are now quoting announced in 1881 that there constantly appear in the excretions of living and healthy animals bodies of the nature of ptomaines. He showed that the alkaloids of the urine discovered by Liebreicht and Pouchet ought to be classed along with the alkaloids of putrefaction

[1] Session January 12-19, 1886. (Journal des Societés Scientifiques, January 13-20.)

already known; similar alkaloids have been found in the saliva and in the muscles; among the latter he designates xanthocreatine, crusocreatine, and pseudoxanthine. Gautier gives to all these the name of *leucomaines* to distinguish them from the cadaveric alkaloids. These divers alkaloids, according to this writer, accumulate in the blood, when for various reasons the skin, the kidneys and the digestive tube fail to eliminate them; they there exercise pathological influences more or less disastrous to the entire economy. Some idea of these effects may be gained by noting the results of the injection in animals of several of these new *leucomaines*, of a perfectly defined and crystalline character, which Gautier has extracted from muscle juice; these results are chiefly somnolence, prostration, sometimes vomiting and purging. The leucomaines are, however, less active than the ptomaines. These alkaloids are incessantly formed during health, and are as much products of disassimilation as urea, carbonic acid, creatine, etc.

According to Gautier, we resist incessant auto-infection by two distinct mechanisms; elimination of the toxic principle, and its destruction by oxygen. Elimination by the kidneys can be proved, and the same experimenter has always detected alkaloids of the nature of ptomaines in normal urine, though in feeble quantity and the proportion materially augments in certain pathological states such as typhoid fever and cerebral diseases.

Elimination by the digestive tube is also probable, but the problem is rendered somewhat complex by the fact that ptomaines are constantly being formed in the intestines owing to the action of bacteria on the fæces, and these alkaloids are likely to be absorbed when any cause prevents their due removal in the stools.

But the most powerful means of elimination of these bases is their constant combustion by oxygen. The greater part of these poisons are very oxidizable, and it is by the vivifying influence of constantly renewed supplies of oxygen in the normal state that they are burned in the blood, perhaps also in the tissues, and disappear. Hence, normally, we find but a small proportion of muscular leucomaines in the urine.

But let any cause, whatever, diminish the access of air to the blood, or let the quantity of hæmoglobin diminish as in chlorosis and anæmia, or let some substance interfering with hæmatosis be introduced and there will soon be an accumulation of azotized substances of the nature of ptomaines and leucomaines. It is in accordance with this theory, says Gautier, that we may explain the nervous troubles of chlorosis, anæmia, pregnancy, and the beneficial influence of respirations of oxygen, the only means thus far known of combating efficaciously this vomiting, which is without doubt provoked by the retention in the blood of a poison imperfectly eliminated, or incompletely burned. "May we not be allowed to ask," adds the same writer, "if fever itself, which coincides with a minimum consumption of aliments and an inversely proportionate increase in the carbonic acid eliminated, and the oxygen consumed, also with a quickened circulation, may not have for its consequence the destruction of a poison which has been formed in excess in the economy?"

The therapeutic deduction which M. Gautier would draw from the above considerations is the beneficial effect likely to be obtained from whatever can excite the functions of the skin, the kidneys and the intestines, and what is perhaps of still more importance the powerful disinfection likely to accrue to the economy from everything which energizes respiration and hæmatosis.

EARLY LAPAROTOMY IN INTESTINAL OBSTRUCTION.

FEW questions of diagnosis and treatment are endued with more interest and importance than those of intestinal obstruction, surrounded as it is, by a cordon of doubt and uncertainty in both particulars. Though the admirable work accomplished by Treves is a most valuable contribution to medical knowledge, since it furnishes data which, at least, familiarize one with what may happen to the intestine, the hard fact, however, still presents itself, that patients are allowed to die with symptoms of intestinal obstruction where an autopsy shows, only too clearly, that a human life could have been saved by a timely and skillful operation. This is wrong, and deserves serious consideration.

The opinion of German surgeons, as expressed at Berlin during the past year, emphasized the necessity of an early diagnosis, since in cases capable of relief through surgical interference, complications — for example, peritonitis and collapse — follow rapidly the primary trouble. Hence, the longer the delay, the less the probability of a recovery. It is not the last stages of these cases, where the stercoraceous vomiting and marked collapse of the victim form a picture so characteristic as to admit of but one interpretation, that are so difficult of recognition; but their early development when the symptoms, few and indefinite, may denote merely a functional derangement requiring simple medicinal treatment, or may be the first premonitions of a hidden danger, destined to jeopardize life, and demanding the most prompt and decisive surgical interference.

To be able to positively assert that one case is a narrowing of the caliber of the ileum, or that another is an obstruction due to persistent omphalo-mesenteric structures is a perfection of diagnostic power, which will be most pleasing when acquired; but at present, such accuracy is of minor importance.

We are first called upon to distinguish cases requiring surgical aid, from those capable of relief by medical treatment; and it is at such times when delay is so vital, and the difficulties and uncertainties of diagnosis are so prominent that the absence of diagnostic power is so strikingly felt. It is also at this moment, that the full value of a laparotomy is realized.

Such means of establishing a diagnosis may seem too heroic; but it is not with any desire to undervalue the aid derived from other methods of examination or exploration, or to relinquish our efforts to discover, if possible, some way less extreme by which these cases can be recognized that we give it such an important place. It is desirable to make an accurate diagnosis if possible without laparotomy, but, if in the present state of our knowledge, that cannot be done, it is preferable to perform it than to run a greater risk of losing a patient through delay. One rarely operates too soon, and often too late. In these cases, a diagnosis must be made, and at once. One cannot wait till symptoms develop which permit an accurate diagnosis regarding the nature of the lesion. An operation, to be successful, must be done early, when diagnosis is difficult. Often while a surgeon waits for definite symptoms the golden opportunity escapes him, and he finds, when the case has developed so far as to present unmistakable signs, that he is too late, and is chagrined to discover, as he stands at the autopsy table of his patient, that a single stroke of his knife would have rescued a human life.

What surgeon in the present time would be justified in neglecting to explore an inguinal tumor of doubtful character when accompanied by acute symptoms of intestinal strangulation? Does he hesitate to dissect down upon such a tumor and relieve the strangulation even though he open the peritoneum? Why then in a case of intestinal obstruction with symptoms almost identical in character and fully as urgent should he hesitate to promptly find the cause by the aid of an exploratory laparotomy? The great difference of opinion on this subject is due to great difficulty in diagnosis, and indications for interference are not continued or stercoraceous vomiting, marked collapse, or symptoms equally prominent, but the failure of ordinary means to relieve. This is the real indication, and it is at this moment that the surgeon can by an exploratory incision, and with comparatively little risk, cut through the cloud, which obscures his vision, with the same stroke that divides the abdominal wall of his patient.

Apparently the reluctance of surgeons to interfere in these cases is due to the following reasons: First, the difficulties surrounding an accurate diagnosis. Second, non-familiarity with a methodical examination of the abdominal cavity. Third, lack of knowledge of what may prove to be the cause of the obstruction. Fourth, absence of technique in overcoming these difficulties.

On the other hand, lives are undoubtedly sacrificed occasionally by rash men who never carefully consider the difficulties a surgeon may be called upon to meet in abdominal operations. Genius and inspiration are often asked to fill the place of careful preparation in these explorations, and certainly in no operation should a surgeon more clearly understand what he may be called upon to do than in an exploratory laparotomy where the possibilities for complications and emergencies are almost unlimited. The trust is great; the care in preparation should be commensurate.

The use of massage, electricity, ice, opium and other modes of treatment are frequently harmful, and waste precious time. Pertinent to the danger of delay is the false security given by opium and stomach irrigations, the former of which masks the dangers, while the latter frequently, by temporary alleviation of the symptoms, deceives as to the nature of the case, or its urgency. From this we are lead to conclude, that should recognized medical treatment, as opium enemata and gastric irrigation fail to relieve the obstruction, laparotomy is indicated in all acute and sub-acute cases within forty-eight hours, especially if the diagnosis be undetermined. Regarding chronic cases, with the supervention of acute symptoms, it would seem that after similar preliminary treatment has been fairly tried without success, operative interference is indicated.

This procedure should be an aseptic one, a median incision is to be preferred as one most favorable to a general exploration of the abdominal cavity, unless some clue to the exact seat of the lesion indicates a particular region as the most direct route to the obstruction. It is exceedingly desirable that the examination of the intestine and abdomen should be systematically and rapidly made. For it is only by following some definite plan that an exploration can be thoroughly performed, and with the greatest economy of time.

Without some such method the operator cannot distinguish parts already explored from those still untouched and thus avoid repetition; there is much unnecessary manipulation of sensitive tissues; the shock of the operation is increased by its increased length; and most important of all, great risk is incurred of failing to find the object of search. Instances are not wanting to show these are no fanciful dangers; and a recently reported autopsy, when an easily reduced diaphragmatic hernia had been completely overlooked during an exploratory operation, serves to illustrate one of them.

The following brief rules for guidance in examining the intestines are suggested: Fix upon the most dilated or congested part of the bowel, and follow it with the finger as a guide to the seat of obstruction — congestion and distension are usually most marked at the point of occlusion, and serve as valuable indices to its site. If this fail, insert the hand and carry it successively to the coecum, umbilicus and sacral promontory. If this again fail, the intestine must be examined throughout its entire length. The starting point of this examination should be accurately located either by the fingers of an assistant, or by some anatomical characteristic. The wound is enlarged if necessary. A coil is drawn out of the abdominal cavity, protected by warm antiseptic napkins, examined and replaced if the result is negative. This is repeated with coil after coil until the obstruction is found. The cause being thus discovered, the subsequent treatment varies with

the character of the lesion, and it is here that the value of a careful previous consideration of possible emergencies demonstrates itself.

The operation is apt to be considered finished by the removal of the cause, but no operation for the relief of intestinal obstruction should be considered complete until the over-distended intestines are relieved. This is a matter of great importance; and Mr. J. Grieg Smith considered this over-distension as exerting an important influence on the amount of relief derived from an operation. This surgeon found by experimentation that an intestine distended by injecting the duodenum extrudes from the half-opened abdominal cavity before the liquid fairly reaches the ileum, and that, with the abdomen fully opened, rupture of the peritoneal coat occurs at many points before the fluid escapes from the anus. He therefore concludes that the acute flexures of the distended intestine, caused by its mesenteric attachment, act as a succession of valves at the points of incurvation of the tube, and thus form an insuperable obstacle to the free action of the over-distended half-paralyzed gut.

Should an intestine be left unrelieved its inability to free itself of its contents would render valueless an otherwise effective operation. From the foregoing one would infer that emesis, either spontaneous or artificial, owes what efficiency it possesses to its power of freeing the dilated intestinal tract of liquids and gases.

In some cases where the condition of the patient contraindicates a prolonged operation, or sudden collapse supervenes, the formation of an artificial anus offers a means of relieving the obstruction, and rapidly terminating the procedure. Recently reported cases prove that this is not the intractable difficulty it was once considered to be, for by a properly performed resection operation it can be closed at some future convenient opportunity.

It may seem superfluous to dwell so much on the necessity for a thorough knowledge of the technique of abdominal surgery in these exploratory operations; but, since shock figures so prominently as a cause of death, and its severity is directly proportionate to the duration of the operation, the surgeon's ignorance of details may turn the scale against recovery by the delay thus caused.

A careful consideration of this whole subject of laparotomy in intestinal obstruction will lead, we think, to the conclusion that timidity and conservatism too often delay or prevent a prompt and beneficent operative interference in these most serious cases.

MEDICAL NOTES.

—Professor Vulpian, of Paris, has resigned from the staff of the Hôtel-Dieu.

— Mr. Wm. T. Evans reports in the *British Medical Journal*, December 19, 1885, a case of a newly-born nursing infant which was fatally poisoned by opium given to the mother for after-pains.

— Professor Bartholow recommends for superficial neuralgia, that a five to twenty-per cent. ethereal solution of menthol be painted over the part.

— "Stammering of the urinary organs" is the apt term applied by Sir James Paget to the cases of difficult urination, wherein no pathological change can be found, where the patient has a difficulty in passing water at certain times and places, while at other times and under other circumstances, no such trouble is experienced.

— Many men who display good sense, prudence, and consideration in all that pertains to others, are foolishly careless about themselves. We learn from the *Philadelphia Daily Times*, that General Hancock seems to have illustrated the not uncommon folly of a man who feels himself "out of sorts," but goes about his daily duties without paying any attention to his health until he suddenly breaks down. It is clear that he had been dangerously ill for a long time, but he never consulted his physician, and his friends supposed that he was merely tired or depressed, and that he would be all right in time. The carbuncle, which was partly a symptom of his general condition, brought him to bed, and then the surgeons who were summoned found that he was incurable.

— At about the first of the year, it was stated in the Consular reports from Spain, that cholera morbus was prevalent in Algesiras, five miles from Gibraltar. On January 18, the Consul reported the disease to be Asiatic cholera, and that twenty-two cases and eleven deaths had been reported, and also, that quarantine had been established at Gibraltar. January 23, the Consul reports that no new cases have been reported for several days. Official reports from Italy state that from November 17, the day on which the publication of the Cholera Bulletins was discontinued, to December 28, there were one hundred and thirteen cases and ninety-eight deaths from cholera in Italy, as follows: In the Province of Palermo, fifty-three cases and forty-eight deaths; in the Province of Venetia, twenty-seven cases and twenty-five deaths; in Treviso, twenty cases and fourteen deaths; in Rovigo, twelve cases and ten deaths; and in Emilia, one case and one death.

— That medical advertising has become one of the fine arts is abundantly shown by the following extract from a pamphlet lately distributed among physicians. "The value of wine as a stimulant, in addition to good food in the enfeebled digestion of the aged, has ever been recognized from the earliest time. Ulysses urges upon his aged father a regimen well suited to his waning energies.

> 'Warm baths, good food, soft sleep and generous wine,
> These are the rights of age and should be thine,'

"And Justus von Liebig pronounced wine to be 'as milk for the aged.' . . . At the present time the growing objection to alcoholic stimulants and the spread of the temperance, or even the total abstinence movement, has limited the resort to wine, and this in turn has led to the selection of substitutes of non-alcoholic char-

acter. For those who decline to accept the aid of wine, as did Timothy, who had to be told to 'Drink no longer water but a little wine for thy stomach's sake and thine often infirmities,' and who need something of a stimulant character in order to rouse the flagging powers of digestion, this syrup offers special advantages; and one or two teaspoonfuls in a tumbler of water, form a bitter tonic, sharpening the appetite, and giving tone to the digestive organs, taken before or with meals."

— The *Lancet* calls attention to the unhealthful conditions prevalent in the vicinity of Sandringham, the Prince of Wales's seat, where the princess and other members of the family have recently suffered from sore throat of a diphtheritic character. The estate of Sandringham includes about 7000 acres. It consists of a large portion of very wild, unreclaimed sporting land, and some rich meadow and pasture and salt-water marshes. The death-rate from diphtheria in this portion of Norfolk is in excess of the death-rate from the same diseases in St. Giles', Shoreditch, Bethnal-green, Whitechapel, or St. George's-in-the-East, which are among the poorest and least sanitary districts of London. Yet here is the home of the Heir Apparent and his family, purchased by the advice of the Government at a cost of £220,000. We cannot suppose that in the house at Sandringham insanitary conditions have been permitted to prevail, for it was here the Prince was so seriously ill from typhoid, by which attention should have been forcibly directed to the sanitation of Royal residences. The Prince Consort lost his life at Windsor, though it is suspected he contracted the disease at Sandhurst. The Prince of Wales nearly lost his life at Sandringham, though it is not quite clear where and how he contracted the fever. The Duchess of Connaught's life was in danger in the newly-erected residence in Bagshot-park; and at last the Princess of Wales has been subjected to risks, and with her in all probability others of the family and the many distinguished visitors who have been at Sandringham since Christmas. Our contemporary suspects the undrained marsh lands in this portion of Norfolk, as elsewhere, to be at the bottom of this diphtheritic tendency, and till they are drained diphtheria will prevail. It adds with what must be a fine sarcasm, that the Prince of Wales can scarcely, with his many duties, be expected either to understand or attend to such matters, but his advisers should. Had the Princess died, what would have been the verdict of the people?

BOSTON.

— His Honor, Mayor Grace of New York, lectured at the Boston Theatre last Sunday evening, in aid of the Carney Hospital. About $2,000 was netted for the hospital.

— A complimentary dinner was tendered Dr. Morrill Wyman at the Parker House last week by the Cambridge Medical Improvement Society. Dr. S. W. Driver presided.

— The trustees of the Boston City Hospital gave a hearing last Friday evening, February 19th, to the remonstrants against the petition that homœopathy should take part in the medical and surgical treatment of patients at the hospital. Members of the Hospital Staff were present by special invitation of the trustees.

— The entire force of the Board of Health has been at work since the inundation in examining the condition of dwelling-places in the district affected by the breaking away of Stony Brook, with a view to expediting the freeing of the cellars from water and the overcoming of dampness caused by the flooding. During last week about one hundred houses were reported upon a day. As fast as the reports are received the owners of houses pronounced defective, are officially notified of their condition. Where the walls of cellars have a coating of escaped sewage, thorough cleansing of the walls is required, after which whitewash is freely applied.

NEW YORK.

— The summary of mortality of the State of New York for the year 1885, as published in the monthly bulletin of the State Board of Health shows that the total number of deaths reported during the year was 80,407. Of this number 30,027, or 37.3 per cent. were in children under five years of age. The number of deaths from the principal diseases, is given as follows: cerebro-spinal fever, 446; typhus fever, 26; typhoid fever, 1,067; malarial diseases, 944; small-pox, 33; scarlet-fever, 1,184; measles, 1,170; erysipelas, 354; whooping-cough, 834; croup and diphtheria, 4,508; diarrhœal diseases, 7,301; acute respiratory diseases, 10,864: consumption, 11,238; puerperal diseases, 974; diseases of the digestive system (not diarrhœal), 4,343; diseases of the urinary system, 4,069; diseases of the circulatory system, 4,903; diseases of the nervous system, 8,651; cancer, 1,887. For the entire State, the ratio per 1,000 of deaths from all zymotic diseases to the total mortality in 1885 is 222.17, against 269.12 for nine months of 1884.

— State Senator Griswold, of Brooklyn, has introduced a bill into the Legislature abolishing the present fee system under which from $50,000 to $100,000 is collected annually by the Health Officer of the Port, and fixing the salary of that official at $10,000 per annum, in addition to an allowance of $6,000 for the expenses of the office, to be expended under his direction. It also provides that there shall be first and second assistant health officers at salaries of $3,000 and $2,000 respectively; and that after the passage of the act no fees or charges whatever shall be collected by the health officer in the performance of his duties. It is very doubtful, however, whether this bill will become a law, as the present large revenues of the office constitute too tempting an object in the eyes of the politicians to be thus summarily dispensed with.

— There is still a good deal of diversity of sentiment with regard to the advisability of constructing the contemplated enormous Quaker Bridge dam in

connection with the Croton water supply. The latest opinion in favor of the project is that of Chief Engineer, Benjamin Church, of the aqueduct service, who in a report submitted at the last meeting of the Aqueduct Commissioners arrives at the following conclusions:

(1) It is the surest and most expeditious means of securing the required storage:

(2) Because it will give the purest water.

(3) Because it gives the best control of storage.

(4) Because it is the best safeguard against the stoppage of the city's supply by a possible failure of dams above, to the injury of the Croton dam.

(5) Because without it the supply of the whole watershed cannot be secured, and the size and cost of the new aqueduct will be rendered unwarrantable.

(6) Because it best preserves the healthful conditions for inhabitants in the Croton Valley by keeping the bottom of the reservoir always covered, and prevents local malarial influences.

Miscellany.

A CASE OF PROTRACTED PREGNANCY.

DR. ARNOLD THOMPSON recently reported to the London Obstetrical Society the following case: — The patient was a delicate woman, not long married, who had had a miscarriage previously, occasioned by a shock. After this, menstruation recurred, and the last period ended June, 1884. Her husband left home a week after, and returned on Monday, June 16th, for one night only, on which coitus took place. He left home the next morning and was away for four months. Soon after the husband's departure signs of pregnancy appeared. Delivery took place April 13th, 1885, 317 days after the end of the last menstruation, or 301 days from the last coitus. The dates were absolutely certain. The child was not weighed or measured; it was a female, and appeared of full average size and weight. According to Prussian law the child would be legitimate; according to Scottish law and the French code, it would be illegitimate; in England its legitimacy would be determined by circumstances.

TUBERCULAR MENINGITIS CURED BY IODOFORM.[1]

A SWEDISH physician, Dr. Emil Nilsson, alleges that he has cured an undoubted case of tubercular meningitis by frictions on the shaved scalp with iodoform ointment (1 to 10). The patient was a boy, aged eight, whose mother had a family history of phthisis, and four of whose brothers and sisters had died from tubercular meningitis. The symptoms in this child's case were similar to theirs,— headache, torpor, convulsions, strabismus, and pyrexia. He was at first treated with calomel and iodide of potassium, but did not improve; and, after having been under treatment a week, became distinctly worse, being unable to take food or medicine. The pallor of the face, which had pre-existed, gave way to flushes of the cheeks. The child threw himself out of bed, and presented several clonic spasms of the limbs and of the facial muscles. The head was then shaved and iodoform ointment rubbed in, an oil-skin cap being put on. The friction was repeated three or four times in the day, and the next day there was a decrease in the convulsive movements, the sleep was calmer, and the spasmodic contractions, which had previously been excited by the slightest noise, now ceased to be so. Consciousness shortly afterwards returned, and the child's face became of a more natural color. This, however, was accompanied with a severe coryza, redness of the lips, and an irritable cough, the breath smelling strongly of iodoform. The ointment was discontinued, and syrup of iodide of iron given. The unpleasant symptoms rapidly disappeared, and the child was soon running about in good health.

NERVE SUTURING.

DR. MICHAEL BEVERLY of Norwich, England, has recently operated with success in a case where the ulnar nerve had been severed by a broken bottle, four months before the operation. A dense cicatrix over the nerve marked the point where the injury had taken place, one and one-half inches above the wrist. There was atrophy of the parts supplied by the nerve, and intense pain when the little and ring fingers were moved.

Under carbolic spray he dissected and found the upper part of the trunk of the ulnar nerve. This was traced down into the tendon of the *flexor carpi ulnaris* with which it was intimately adherent, and accounted for the intense suffering caused by movements of the little and ring fingers. He then dissected until he found the long portion of the ulnar trunk which had retracted and lay just above the annular ligaments. A clean section was made at the end of each part of the nerve trunk and the two fresh surfaces were united by two catgut sutures. The arm was placed on a splint and the hand kept in a flexed position. The wound healed by first intention. Sensation gradually returned into the parts from which it was absent, and it is now, two months after the operation, nearly restored. There is very little difference now between the two hands in either sensation or motion.

THE JUMPERS.

DR. J. D. THORNTON, of the U. S. Marine Hospital Service, gives some account in the *Medical Record*, of the French-Canadians who are victims of that form of hysterical disease recently described under the term miryachit. This affection, characterized by an uncontrollable impulse to imitation, has been noted among the Canadian-French lumbermen who go over into Maine for work. The cause which the writer assigns for the disease is worthy of note, though it seems rather inadequate.

"I had from time to time," says Dr. Thornton, "heard lumbermen and others, whose avocations lead them to spend much time among the French camps, speak of these 'jumpers,' but had given no credence to the, as I thought, absurd stories they related in regard to them, until one day, while attending to my duties in the waiting-room of my fumigating station, I incidentally let fall the window near my desk, by turning

the button suddenly, thus letting the frame fall a short distance, making a quick, sharp noise, when three out of seven French-Canadians who were sitting near, awaiting their certificates of inspection, leaped into the air as if they had been shot, at the same time uttering a yell which would have done credit to a North-American Indian. From that time, I was on the watch for these strange characters, and, when possible, made inquiries of them through my interpreter, in regard to the cause of their condition. Before speaking of this, perhaps it will be well to enumerate some of the manifestations which give them the characteristic name of 'jumpers.' One or two instances will be sufficient. Recently, one of them, a French-Canadian of small stature, came out from an adjacent camp to the post-office. Just as he was about to ask the postmaster for his mail, he being a total stranger to the official, a man of sixty-five years of age, some one knowing the fellow to be a 'jumper,' mischievously cried out, 'Grab him by the throat!' The fellow sprung like a cat, and grasped the old man by the throat, and held on until removed, the irate postmaster pouring forth torrents of invectives on the poor fellow, who really was perfectly guiltless. Another unfortunate wood-chopper had just come into camp from two day's work, and was standing near the large camp-heater, in which was a very hot fire, when some one cried, 'Grab the furnace!' No sooner were the words said, than the poor fellow obeyed the order, and, as a result, left a scorched pattern of each hand on the nearly red-hot pipe, thus rendering him unfit for his work in the woods for some weeks. I could, were it not for taking up valuable space, enumerate instance after instance fully as peculiar as the above. In brief, it may be stated that at any time and under any circumstances, with the slightest provocation, and almost instantaneously on being spoken to, one of these fellows will obey any command, imitate any action, without regard to its nature, trivial or serious. He will leap on to a table, or over a stove, or into a river or pond; throw any article or weapon he may have in hand in any direction indicated; will repeat any sentence or exclamation. So serious a matter is this, that many of the lumbermen absolutely refuse to admit a man known as a 'jumper' into their camps. I find they are not wholly confined to French-Canadians, as occasionally a Canadian of Irish parentage will exhibit the same symptoms. As stated above, I have endeavored, when possible, to investigate as to the cause of this peculiar and distressing condition; and while I find, without doubt, that primarily, it is due to an inherited nervousness, the immediate cause is in taking such children, when small, and, while firmly held, tickling them until convulsive symptoms appear. This seems to be the story of such ones as I have made inquiries of. Whatever the cause, the condition is one much more easily acquired than lost, as it firmly clings to its victim far into adult life."

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 13, 1886.

Deaths reported 1,914: under five years of age 639; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 286, consumption 305, lung diseases 312, diphtheria and croup 138, scarlet fever 37, diarrhœal diseases 24, whooping-cough 22, malarial fever 17, erysipelas 12, cerebro-spinal meningitis 10, measles five, puerperal fever three, small-pox two. From diarrhœal diseases, New York nine, Boston and New Orleans five each, Brooklyn four, District of Columbia one. From whooping-cough, New York 16, Brooklyn five, District of Columbia one. From malarial fever, New York seven, Brooklyn and New Orleans five each, Springfield and New Bedford one each. From erysipelas, Brooklyn four, New York three, Boston, two, Lynn, Chelsea and Taunton one each. From cerebro-spinal meningitis, New York three, Fall River two, New Orleans, District of Columbia, Nashville, Lowell and Springfield one each. From measles, Brooklyn, Boston, Baltimore, District of Columbia and Lowell one each. From puerperal fever, District of Columbia two, New York one. From small-pox, New York two.

In 109 cities and towns of Massachusetts, with a population of 1,250,326 (population of the State 1,941,465), the total death-rate for the week was 14.25 against 16.59 and 18.23 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending January 30th the death-rate was 22.1. Deaths reported 3,850: infants under one year of age 862; acute diseases of the respiratory organs (London) 478, whooping-cough 168, measles 75, diarrhœal diseases 31, scarlet fever 29, fever 28, diphtheria 23, small-pox (Liverpool five, Nottingham one) six.

The death-rates ranged from 14.4 in Hull to 33.0 in Preston; Birkenhead 21.9; Birmingham 21.4; Leeds 17.7; Leicester 15.3; Liverpool 24.6; London 22.2; Manchester 23.5; Nottingham 21.1; Sheffield 24.8; Sunderland 20.1.

In Edinburgh 16.6; Glasgow 26.6; Dublin 3.19.

For the week ending January 30th in the Swiss towns, there were 30 deaths from consumption, lung diseases 30, diarrhœal diseases 18, whooping-cough seven, diphtheria and croup five, small-pox four, typhoid fever two, puerperal fever two, erysipelas one.

The death-rates were: at Geneva 24.0; Zurich 13.4; Basle 14.8; Berne 31.0.

The meteorological record for week ending February 13, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Feb. 13, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION. — There will be a meeting of the Section at 19 Boylston Place, on Wednesday evening, March 3d, at 8 o'clock. Communications: Dr. G. H. Monks, "Rupture of the Biceps, with Cases." Dr. J. E. Kelly, "An Apparatus for the Treatment of 'Colle's Fracture,' and one for Fracture of the Clavicle." Dr. E. O. Otis will exhibit Dr. F. N. Otis' Improved Evacuator.

S. J. MIXTER, M.D., *Secretary.*

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, March 1, 1886, at 8 P.M. Readers: Dr. J. W. Elliot, "A Case of Salpingitis, with Severe Symptoms: Removal of Tubes and Ovaries: Recovery." Dr. J. Orne Green, "Some of the Less Common Forms of Mastoid Disease."

H. L. BURRELL, *Secretary.*

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Eighty-Seventh Annual Session held at Baltimore, Md., May, 1885.

Local Anæsthesia in General Medicine and Surgery. Being the Practical Application of the Author's Recent Discoveries. By J. Leonard Corning, M.D. New York: D. Appleton & Co. 1886.

The Diagnosis and Treatment of Diseases of the Ear. By Oren D. Pomeroy, M.D., etc. With one hundred illustrations. Second Edition revised with Additions. New York: D. Appleton & Co. 1886.

Prevention of Yellow Fever. Commercial Relations with Brazil as affected by Quarantine Regulations. Brazil and New Orleans.

The Sanitary Protection of New Orleans, Municipal and Maritime. By Joseph Holt, M.D., President of the Board of Health of the State of Louisiana. Read before the American Public Health Association, Washington, D.C., December 10, 1885. (Reprint from the Sanitarian, January, 1886.)

Editorial Reprints from the Journal of Inebriety. I. D. Crothers, Editor, Hartford, Conn., Hallucinations in Inebriety.

A Treatise on Bright's Disease of the Kidneys, its Pathology, Diagnosis and Treatment. With Chapters on the Anatomy of the Kidney, Albuminuria and the Urinary Secretion. By Henry B. Millard, M.D., A.M. Second Edition, Revised and Enlarged. New York: Wm. Wood & Co. 1886.

Medico-Chirurgical Transactions. Published by the Royal Medical and Chirurgical Society of London. Volume the 68th. London: Longmans, Green & Co. 1885.

Catalogue of the Pathological Museum of the Western Infirmary, Glasgow. Compiled by Joseph Coats, M.D., Glasgow. 1885.

Washington Obstetrical and Gynæcological Society. Third Annual Address of the President, Samuel C. Busey, M.D. The Hygiene of Pregnancy. (Reprinted from American Journal of Obstetrics, January, 1886.) New York: Wm. Wood & Co. 1886.

Constitution and By-Laws of the State Board of Health, and Vital Statistics of the Commonwealth of Pennsylvania. Harrisburg. 1885.

ADENOID VEGETATIONS IN THE NASO-PHARYNGEAL CAVITY.[1]

BY FRANKLIN H. HOOPER, M.D., BOSTON.

AMONG the many benefits to be ascribed to the introduction of the rhinoscopic mirror as an instrument of diagnosis, the discovery of the disease which forms the subject of this paper deserves the first place. Although a recently recognized affection, it has been thoroughly described in all its details, notably by Meyer (Copenhagen), Loewenberg (Paris), and B. Fraenkel (Berlin), besides receiving exhaustive treatment in standard text-books on diseases of the throat and nose, especially in those by Cohen and Morell Mackenzie. Little or no mention, however, is made of it in works on general medicine and surgery, yet it is a disease of general interest, leading oftentimes to grave constitutional disturbances, the true origin of which may for a long time escape detection. Being a disease essentially of early life, it is encountered for the first time oftener by the family practitioner than by the specialist, and the fact that it has this general bearing is my excuse this evening for "threshing straw already thrice beaten by the flails of other laborers in the same field."

The seat of the exuberant overgrowth of glandular tissue to which Wilhelm Meyer, in 1868 gave the name of *adenoid vegetations*, is the naso-pharyngeal cavity — a cavity not always looked into in the dissecting-room or on the autopsy table, and one of the last of the body to have light thrown upon the pathology of the diseases peculiar to it.

Situated behind and above the soft palate, the naso-pharyngeal cavity extends from the posterior openings of the nasal chambers to the free border of the palatal curtain. Its shape is constantly changing during life, owing to the movements of the soft palate. A cast of it taken after death, however, like the one I have here in fusible metal from Dr. Mixter's collection, shows that it is an irregular cube, but, on account of certain anatomical structures found in its different regions, it is convenient to describe it as dome-shaped, consisting of a vault or roof, with lateral and posterior walls.

In the vault we find the "third tonsil," an accumulation of adenoid tissue almost identical in structure with the faucial tonsils, and called more frequently the pharyngeal or Luschka's tonsil. On the lateral wall the same adenoid tissue is found around the Eustachian orifices, especially on the Eustachian prominence and in the fossa of Rosenmüller — the recessus pharyngeus — immediately behind it. This lymphatic tissue is distinctly traceable downward along the posterior edge of the soft palate, around the posterior pillars of the fauces to the faucial tonsil, then directly across the base of the tongue and back in a similar manner to the vault, so that the cavity is encircled by glandular tissue — Waldeyer's lymphatic ring of the pharynx — certain portions of which, as the roof, the Eustachian prominence, and the fossa of Rosenmüller being much more richly supplied with follicles than others.

In Dr. Whitney's abstract[2] of Bickel's paper "On the Extent and Connection of the Lymphatic Tissue in the Pharynx," it is stated that only the tonsils of the pharynx deserve the name in addition to those of the fauces, while the follicular glands of the other regions are transitional forms from a simple infiltration of adenoid tissue. But these follicles when hypertrophied, as in pronounced cases of adenoid vegetations, may be found in any part of the naso-pharyngeal cavity, their structure as revealed by the microscope differing very little except in the abundance of the connective tissue between the follicles, and in the character of their epithelial covering. These differences also distinguish them chiefly from the faucial tonsils.

The specimens under the microscopes show these features very distinctly. The sections of the faucial tonsil closely resemble the appearances described and pictured by Stöhr.[3] Its covering of flat epithelium will be seen to be permeated by leucocytes, which, according to Stöhr, are constantly wandering out from the centre of the tonsil through the cement between the epithelial cells, and appearing in the cavity of the mouth as mucous and salivary corpuscles. The epithelial covering of the pharyngeal tonsil will be seen to be of the ciliated variety; otherwise all the specimens are identical in consisting of the adenoid tissue of His plentifully supplied with blood vessels. The difference in the consistence of this glandular tissue in the different regions depends upon the amount of connective tissue it contains.

The presence of this adenoid tissue in the naso-pharynx is subject to the same variation as it is lower down in the pharynx. The vault is often seen to be as smooth as is here represented in this diagram, or, we may meet with the pharyngeal tonsil as large or even larger than is shown in this longitudinal section of a child's head, kindly lent me by Dr. Dwight. The follicles in any part of the lymphatic ring or on the posterior pharyngeal wall may become hypertrophied; even those at the base of the tongue have been of such size as to depress the epiglottis, and interfere with the movements of the larynx. Adenoid vegetations, then, are abnormal developments of normally existing elements.

The growths vary in shape, size, consistence, and color. They may be pendent and hang down into the cavity, as Voltolini expressed it, like stalactites, or they may be cylindrical, with a broad attachment. When limited to the vault, the pharyngeal tonsils may assume many shapes, from being single, with a smooth covering, to being bi-lobed, rough, or made up of many layers of tissue, separated by deep fissures. The color depends upon their vascularity, and varies from a pale to a deep red. There is often seen a small increase of the adenoid tissue at the vault of the pharynx which probably gives rise to no injurious effects, but my present remarks refer to those cases in which the vegetations are sufficiently abundant to fill the naso-pharyngeal cavity, thereby "causing the voice to be dull and nasal in tone, the respiration to be buccal, frequently inducing deafness by setting up inflammation of the middle ear, and in the case of children often giving rise to the constitutional phenomena which follow prolonged nasal obstruction." (Mackenzie).

We owe our knowledge of this disease to European writers. First discovered on the continent of Europe, it is there that it is most frequently seen, certainly much oftener than in this country. Czermak, to

[3] Virchow's Archiv., Bd. 97.

whom we are indebted for the rhinoscope, was the first to see these vegetations in the living subject. This was in 1860. Türck, Loewenberg, Voltolini, and Semeleder soon followed with reports of other cases. Sir Andrew Clark wrote briefly upon this affection under the name of Naso-Palatine Gland Disease in the first volume of the London Hospital Reports, published in 1864, but it was not until 1868 that a complete description of adenoid vegetations was given by Meyer, of Copenhagen.

Lymphoid tissue in the naso-pharynx, as in other parts of the body, tends to disappear after puberty, and the majority of patients having adenoid growths are under fifteen years of age. The youngest case I have seen reported was one by Woakes of an infant aged nine months, and the oldest, a man aged fifty-three, mentioned by Loewenberg. My own cases have ranged between the ages of four and twenty. Sex is without influence, as well as social position, the rich and the poor suffering alike. Heredity and family disposition play an important part, as many instances have been recorded where one of the parents and several of the children have been afflicted. Loewenberg believes that the lymphatic temperament predisposes to it, while others hold that it is entirely independent of any lymphatic or scrofulous diathesis. We certainly find adenoid vegetations in children who are otherwise perfectly healthy and without any of the manifestations of scrofula.

The affection is congenital, although it rarely leads to any marked disturbance before the age of four, and is probably, as B. Fraenkel suggests, special of its kind. A cold, damp climate is said to be favorable to the growth and development of this follicular tissue, as well as chronic catarrhal inflammation of the naso-pharyngeal mucous membrane. These conditions are certainly found in abundance on our own coast, where the climate does not seem to have undergone much change since the author of "Elsie Venner" wrote that "it gives people their choice of dysentery or fever every autumn, with a season ticket for consumption good all the year round," and with regard to catarrhal affections of the naso-pharynx, a specialist of such wide experience as Morell Mackenzie was so impressed while on a visit to this country, by certain subjective noises which he heard during his travels, and which unmistakably pointed to some irritation of the naso-pharyngeal region, that immediately on his return to London, he delivered a lecture on our national affection — post-nasal catarrh. Notwithstanding these supposed favorable conditions, I am led to judge from my own experience and from conversation with others that adenoid vegetations are by no means so common in this country as in Northern Europe.

Several years ago, Meyer, of Copenhagen, had private records of about two hundred cases, and in examining the school-children of his own city and of Stockholm, he found the growths present in one per cent. In Leyden, Professor Doyer states that five per cent. of the children have characteristic faces and pronunciation. Lange, of Copenhagen, has had about four hundred cases requiring operation. Schmiegelow, of the same city, finds that in his clinic, of all patients with diseases of the pharynx, 37.9 per cent. have adenoid vegetations. Hopmann, of Cologne, has operated on two hundred and thirty-four cases. Trautmann, of Berlin, reports one hundred and fifty. Out of the last wo thousand patients that have come under my own observation in the throat clinics at the Boston City and Massachusetts General Hospitals, and in private practice, twenty-eight have had these growths.

Gleitsmann, of New York, in his report of the Throat Department of the German Dispensary for 1885, notes eighteen cases in a total of 2,042 patients, or about one in every one hundred and thirteen. Tauber, of Cincinnati, has found the vegetations in six tenths per cent. of his cases. Beverley Robinson, of New York, speaks of the rarity of this affection. Swinburne, on the other hand, met with adenoid growths in one out of every ten of his patients, at the Harlem Eye, Ear and Throat Infirmary. The difference in these observations arises, as Robinson explains, from our not all having the same idea of what should be called an *abnormal* growth of adenoid tissue. My own figures refer solely to those cases in which the pharyngeal tonsil was sufficiently large, or the vegetations sufficiently abundant to destroy the functions of the naso-pharygeal cavity, and where their removal was imperative. The symptoms vary in intensity, according to the size and situation of the growths. Loewenberg estimates that deafness is present in three-fourths of all cases. Oftentimes, it is the defect in the child's hearing that first alarms the parents, and leads them to seek advice.

Impairment of the hearing may be produced in many different ways. The vegetations may be so situated that they hang down over the Eustachian orifice, thus mechanically preventing the proper ventilation of the middle ear; or the inflammation of the surrounding tissues, which is always present, may extend into the Eustachian tube, causing swelling of its walls and its partial or complete closure. Again, catarrhal or suppurative processes may be excited in the tympanic cavity itself, accompanied by all the sequences of chronic otorrhœa. Middle-ear disease, furthermore, may be produced in a manner to which our attention has been directed by Mackenzie, of Baltimore, namely, through the reflex agency of the vaso-motor and trophic nerves, the circulation and nutrition of the aural chambers being affected reflexly from the inflammation in the posterior portions of the nose.

Finally, these growths may cause paresis of the palato-tubal muscles, and, therefore, be one factor in the production of the so-called "paretic deafness." The deafness in these cases, is always worse with each succeeding attack of coryza. Meyer mentions two symptoms frequently accompanying the use of the ear catheter, which he considers almost pathognomonic, namely:

"(1) The stream of air, after having passed freely into the tympanic cavity — as found by auscultation — will suddenly stop, and after a little while, flow on without any obvious reason, as freely as before.

"(2) A gurgling or bubbling sound of thick mucus behind the nasal cavity is heard during insufflation, and sometimes, bubbles of the same viscid mucus will appear at the nostril through which the catheter has been introduced."

He also lays down the general rule that a deaf patient who breathes through the mouth and has a thin, compressed nose, is affected with adenoid vegetations in the naso-pharyngeal cavity.

The prognosis of this form of deafness is very favorable, when the vegetations are discovered and removed in good season; consequently, a careful exploration of the naso-pharynx in such cases, should never be omitted. Mouth-breathing — one of the worst of bad

habits — is constant in this affection, and unavoidable. A glance at this frozen section of a child's buccal cavity (also from Dr. Dwight's collection), will show how completely it is filled by the tongue and soft parts, making of it, when the lips are closed, a practical vacuum; yet in the infant, the tongue is larger in proportion to the cavity of the mouth, than in the adult, and we have Kussmaul's authority for the statement that even though a suckling may be sleeping with its mouth open, it is breathing, nevertheless, exclusively through the nose. New-born animals on whom the experiment has been tried, soon die from asphyxiation if their nostrils be plugged with cotton-wool, and we may say that the younger the mammal, the more important it is that the nasal passages should be free, since the nursling cannot otherwise properly procure its nourishment, for in infancy, we know, the mouth is little else than a suction-pump, the tongue being the piston, and that the successful working of the apparatus depends upon an unobstructed passage of air to the lungs through the nose.

But the effects of nasal obstruction are direful enough when they are due alone to the derangement of the air-supply. The facial expression of the mouth-breather is one of stupidity. The buccal cavity, as we have seen, being practically a vacuum, the lower jaw is held against the upper, not by any conscious muscular effort, but by atmospheric pressure. When, however, the nose is impervious to the passage of air, or partially so, the lower jaw falls from its own weight. The face being constantly acted on by gravity, becomes elongated, the lines at the angles of the mouth and nose, and in aggravated cases, at the corners of the eyes, being especially deepened and stretched. These furrows reflect the light in such a manner as to make the face look dull,[4] which, added to the open mouth, sunken cheeks, and pinched nose, convey an impression in pronounced instances, almost of idiocy. Yet this facial expression, sometimes mistaken as indicating mental deficiency, is produced in as purely a mechanical manner as in the circus clowns, on whose face paint is daubed in exactly the same regions, in order to give to his countenance a look of vacancy and imbecility.

One author has attributed the fact of his having more females than males among his patients with adenoid vegetations, to this external effect of mouth-breathing upon the personal appearance. But the remote effects of this destructive habit are more to be dreaded, and more important to avoid. Air which enters the lungs of the mouth-breather is not only less in quantity than if it passed through its natural channels, the nasal-chambers, but its quality is altered and vitiated, being charged with impurities which would have been arrested and ejected by the cilia lining the nasal passages, being colder than if it had been warmed by the extensive blood-supply of the tissues covering the turbinated bones and other portions of the nasal cavities, and being dryer than if it had taken up moisture, as it should, from the mucous glands in the respiratory tract in the nose. The mouth-breather, accordingly, is undergoing a sure, but fortunately, a slow process of asphyxiation. He is not getting a sufficient quantity of air to expand the lungs and oxygenate the blood, and what he does get is impure. Deformities of the chest-walls, malnutrition, deafness, loss of appetite and sleep, may supervene before the obstructive cause in the nose is discovered, which, when removed, enables the individual, for the first time in his life, to experience what it means "to take a full breath."

Major,[5] of Montreal, has noticed the damage done to the teeth by mouth-breathing, and considers it the "result of dryness, caused by the passage of air between and around them, facilitating the decomposition of any food present, and favoring the formation of acids capable of reacting vigorously." He speaks of the changes as confined to the upper incisiors, the lower teeth escaping injury, as they are protected by the lips and tongue, and moistened by the saliva. In one of my own cases, a lad, aged fifteen, who had been a confirmed mouth-breather for eight years, the teeth in both jaws presented a peculiarly notched and carious appearance. They were very brittle, and more than one had broken off while he was eating.

The teeth of the first dentition were healthy. As the permanent set came through the gums in their present wretched condition, and as there was no evidence of any syphilitic taint, the deficient calcification was probably due to the general low tone of the boy's system, brought about by buccal respiration. Adenoid vegetations have a marked effect upon the speech and tone of the voice, because their presence destroys the virtue of the naso-pharyngeal cavity as a resonator. The voice, instead of being clear, is muffled and stuffy, readily explained by the sound-waves impinging on these soft, irregularly-shaped, glandular masses, instead of on the normal, smooth walls of this dome-shaped resonating chamber. Certain words are enunciated with difficulty and imperfectly, and the nasal consonants, "m" and "n," and "ng," cannot be pronounced at all. The word common is pronounced "cobbod;" nose as "doze" or "loze;" and song, "sogg," etc.

Snoring always accompanies this form of nasal obstruction, and is so loud as to disturb not only the sleep of the child, but even that of persons in neighboring rooms.

Children, then, in whom the glandular tissue in the naso-pharnyx is in excess, are exposed to a long train of sad sequelæ, and I think the following statements, which I translate from B. Fraenkel's paper on this subject, will not be considered exaggerated by any one who has had experience with this affection in the young. He says:

"I have already pointed out that their facial expression is one of stupidity, that in consequence of loss of sleep, they present a tired and sad appearance; also, that their speech is affected. Adding now, to these, deafness, the children sometimes convey the impression of being idiots, and, indeed, this is not merely an impression, but it is a fact that their intelligence may become weakened, and their characters changed. They do not progress in their studies at school, are generally at the bottom of the class, and remain in it longer than the prescribed time. . . . That the impairment of intellect and want of energy manifested by these children is real, and not merely in the expression of the countenance, is made evident by watching these same children after the growths have been removed. To the gratification and astonishment of the parents and teachers, the children hitherto sluggish and dull of comprehension, now make rapid progress, and their comrades soon cease to make a laughing-stock of them. It seems, in fact, as if, through the removal of the ob-

[4] Warner's "Physical Expression," International Scientific Series, Vol. 12, 1886.

[5] New York Medical Record, November 22d, 1884.

structing vegetations in the naso-pharynx, they had become different beings."

Again, speaking of the nervous symptoms sometimes associated with this disease, such as abnormal sensations in the head, a feeling of weight and pressure in the upper and back part of the cranial cavity, melancholia, headache, etc., Professor Fraenkel continues: "The children come from school complaining of pain in the head, with a desire to lie down, and occasionally vomit, yet on the next day, they have sufficiently recovered to go again to school. Slight fever sometimes accompanies these attacks. In many cases, the parents and physician content themselves with the diagnosis of 'migraine,' in explanation of these oft-recurring attacks. The children pass their holidays in the country or at some health resort, where they are comparatively free from such attacks, yet they return home, bringing their old trouble with them. Then it is said, 'the child cannot bear the air of the school-room.' Finally, the adenoid vegetations are detected and removed, and the child is restored to perfect health."

However strongly we may suspect the presence of these growths, the diagnosis cannot be established with absolute certainty without exploring the naso-pharyngeal cavity. This may be accomplished either by posterior rhinoscopy, or by means of the index finger, introduced behind the soft palate. Unless there is some anatomical obstacle to the use of the rhinoscopic mirror, I believe it is the exception, even in young children, that we cannot, with a small expenditure of time and patience, succeed in employing this method. The posterior nares can then be examined leisurely on the part of the operator, and with no discomfort to the patient. In my judgment, it is much more satisfactory in the end, to train the patient to bear a rhinoscopic examination, than to rely upon the finger for information regarding the condition of this cavity. The latter procedure is not merely disagreeable for the patient, but the operator, with the aid of a post-nasal probe, can acquire a more vivid and accurate picture of the number, size, shape, and situation of these vegetations through the sense of sight, than by the sense of touch. Digital exploration I never resort to, unless it is impossible to use the mirror. In such cases, the sensation communicated to the finger by these glandular masses is very characteristic; they feel, as Meyer describes it, like a bunch of earth-worms.

The treatment of the growths, when sufficiently large and numerous to obstruct nasal respiration, consists in their removal. To effect this, many methods have been recommended, some requiring the use of the rhinoscope, and others not; and many different instruments are successfully employed by different operators, such as the curette, the ring-knife, the sharp spoon, the cautery or cold snare, the finger-nail, or a scraper carried on the end of the finger, and the post-nasal cutting forceps. It makes, of course, but little eventual difference to the patient, provided he is relieved of the growths, whether they have been scraped off, pulled off, snared off, or cut off; or whether the surgeon operates with or without the rhinoscopic mirror.

But as the advance that has been made in our knowledge of the diseases of the various cavities of the body, is directly attributable to the fact that certain instruments, have, from time to time, been added to our armamentarium, which permit us to illuminate these cavities, it seems to me, that in performing operations in them, we should avail ourselves of such instruments, when possible, in order to be able to see exactly what we are about. There is, however, a great difference in the size, and some variation in the shape of different naso-pharyngeal cavities, to say nothing of the excessive nervous irritability of some patients, or of the intractability of others. The difference in the consistence of the growths, their size, mode of attachment and situation, must also be taken into account. No one operative procedure, therefore, if we regard the patient's or surgeon's comfort, is applicable to all cases.

After having tried most of the methods recommended, the following has yielded the best results in my own hands, and can be employed in the majority of instances. The patient is easily taught to hold the tongue well depressed in the floor of the mouth, by means of one of the ordinary spatulas — preferably, Türck's. The operator now has both hands free, one for the rhinoscopic mirror, and the other for the post-nasal cutting forceps, either Cohen's or Loewenberg's. It is necessary to have these forceps of different sizes and curves, to suit individual cases. A strong light being reflected into the cavity, the instrument, guided by the image in the mirror, grasps the vegetation, and if it be soft or pendulous, it is torn off, care being taken not to use force; or if it be hard, and of the flat variety, it is cut off. Occasionally, too large a quantity of the mass becomes engaged between the blades of the forceps, and, not coming away with easy traction, the blades should be released and re-applied to a smaller portion of it.

In conjunction with this method, one of the forms of nasal snares, or écraseurs, armed with No. 5 piano-wire, is very useful to remove growths which are too tough to be brought away with the forceps. The snare being introduced anteriorly through the previously cocainized nostril, the loop can be watched in the rhinoscopic mirror, and directed to the desired vegetation or pharyngeal tonsil. When the naso-pharyngeal cavity is very long, and the remaining portions of the growths are high up and on the sides, the snare used as described is a convenient way to get rid of them. If one operates in this manner, every movement of the forceps or the snare can be watched, and a few pieces can be removed at each sitting until the cavity is completely freed of the growths. The patient's visits are renewed sometimes daily, or at intervals of two or three days, without apprehension or dread of the operation, as the pain is usually slight if healthy parts are not nipped, as they ought not to be if the rhinoscope is used. The hæmorrhage, more or less, according to the individual, has always been insignificant in my own cases. Once thoroughly eradicated, I have never seen a recurrence of the growths. But we may meet with these adenoid vegetations in children whose naso-pharyngeal cavities are too small to admit of the procedures just mentioned, or who obstinately refuse all co-operation.

When they are very refractory or nervous, it is advisable to administer ether, and, with the post-nasal forceps, remove the entire mass at one sitting. The specimens I show you give an idea of the quantity contained in the naso-pharyngeal cavities of four children from six to eight years of age, who were recently relieved of their exuberant tissue in this manner. Rhinoscopy being out of the question in these cases, the practised hand can feel when the end of the forceps is embedded in the tissue. It is well to hold the soft palate for-

ward by means of a palate-hook, or, if space permits, the forceps may be guided by the index finger of the opposite hand. The hæmorrhage may be considerable, but ceases immediately. Other children, ranging from the ages of four to fifteen, I have found most tractable, and when old enough to comprehend the nature of their trouble and the object of the operation, only too willing to lend their aid.

For the after-treatment of the seat of the vegetations, a mild astringent and detergent wash is all that is required, while the treatment of the complications in the nose or other parts, must be conducted on general principles. There is an unfortunate belief prevailing among the laity, that that bugbear "catarrh" is some incurable disease, and one we must submit to with resignation. Little cognizance is taken of the different varieties of nasal affections, or of the advance that has been made in recent years in the surgical treatment of the catarrhal diseases of this important organ. In typical cases of adenoid vegetations, the symptoms of "catarrh" of the most aggravated form may be present, yet the good effects of treatment are noticeable, even before it is completed; and I think it may be safely said that there is no other disease in the domain of him who confines himself to the upper respiratory tract, the treatment of which is attended with more satisfaction to the operator, or with more permanent relief to the patient.

SEVERE HÆMORRHAGE FROM ANTE-PARTUM SEPARATION OF THE PLACENTA, WITH THE INFUSION OF SIXTY-SIX OUNCES OF SALT SOLUTION.

BY F. B. HARRINGTON, M.D.

MRS. H. is twenty-three years of age. She first came under treatment in January, 1885, suffering with a slight endometritis. She became pregnant for the first time in June. There were no unusual signs during pregnancy until February 6th, about a month before the expected time of delivery. At five P. M., on that date, after lifting some small article, she felt a severe pain in the back. This continued for over a half hour, when there was a sudden rush of blood, wetting the clothing. The flow continued until nearly a pint of blood was collected in a basin. She became faint and was put to bed. When first seen at 6.30 P. M., a large surface of blood was found upon the bed and the night-dress was soaked up to the waist. The pulse was 78 and of good strength. The pains were strong and nearly constant. The uterus was low down in the pelvis, the cervix was hard and unchanged by the pains and the os was wholly undilated. After much effort the tip of the finger was inserted into the os. For an hour and a half the finger was thus held, and, although little progress toward dilatation was made, the escape of any large quantity of blood from the uterus was prevented.

It was impossible at this time to push a single finger into the internal os. There was no perceptible change in the condition of the cervix. No fœtal movements were felt and the unceasing pains prevented the hearing of the fœtal heart. This condition of the patient continued until 9.45 P.M., when there was a sudden profuse hæmorrhage which weakened her at once. She became blanched and the pulse quickly rose to 120. Immediate emptying of the uterus became absolutely necessary. The finger was again pushed into the os, and the escape of blood from the uterus was prevented.

Dr. Strong, who was sent for, arrived soon after 10 P.M. The patient was etherized at once. The dilatation of the cervix was most difficult. It resembled the virgin cervix rather than that of a woman pregnant for eight months. During the efforts at dilatation the loss of blood was excessive. The sheets having become soaked in blood, three pints by measure were caught in basins. At length a single finger could be made to reach the internal os. A head was felt fixed against this. The pains were incessant. The uterus seemed tonicly contracted, and because of this, and for fear of delay in turning, the membranes were not ruptured. Slowly a second and third finger were introduced by the use of the utmost force. When it became possible to sweep the finger about the lower segment of the uterus, a perfectly smooth wall was met on all sides, showing that the placenta was high up. The rush of blood continued and stood in pools on the carpet. The patient was greatly collapsed; she was colorless, covered with cold sweat and breathing rapidly. All the force that could be used was brought to bear upon the cervix, and just as an incision was about to be made the tissues yielded, and a large rent allowed the hand to be pushed into the uterus. The membranes were ruptured. There was a small rush of waters. The feet were easily found and the child was quickly turned and delivered, but was dead. When the feet were drawn into sight, the placenta appeared preceding the body of the child. The uterus contracted quickly and well. A subcutaneous injection of whiskey and one of ergot were given at once. Hot water with vinegar was injected into the uterus. A steady flow of blood continued although the body of the uterus was well contracted. A Sims' speculum was inserted but no bleeding point could be found in the torn cervix.

A swab covered with powdered persulphate of iron was inserted several times into the cavity of the uterus, and applied to the cervix. This controlled the hæmorrhage.

The condition of the patient was extremely alarming. Only the flutter of a pulse could be felt in the wrist. The patient was inverted and the legs were bandaged from toes to hips. Subcutaneous injections of ether and whiskey were repeatedly given, but the patient, perfectly blanched and almost pulseless, began to gasp and to toss for breath. It was now forty-five minutes since the birth of the child and the patient was sinking. It was decided to try infusion. The right median cephalic vein was exposed and raised upon a director and a ligature was passed beneath it. A funnel and a connecting rubber tube and needle were filled with a solution of salt and water. The needle was tied into the vein. Thirty-six ounces of the salt solution were poured into the vein in about twenty-five minutes. The first few ounces brought the pulse back to the wrist, and the tossing and gasping ceased. Within twenty minutes a slight flush could be seen in the cheeks and the lips took on a little color. The pulse fell to 120 and was of fair strength. The patient was perfectly conscious and took stimulants by the mouth.

There was still no loss of blood and the uterus remained hard and small. The color in the cheeks did

[1] Read, by invitation, before the Obstetrical Society of Boston, February 13, 1886.

not remain long, but the patient was quiet and seemed to be resting easily. It was now an hour and a half since the birth of the child and the uterus had remained well contracted. All seemed to be going well, when suddenly the uterus was found to be enlarging. At the same time blood appeared trickling from the vagina. The uterus did not become larger than a cocoa-nut, but the hæmorrhage was profuse. Fresh pledgets of cotton with persulphate were crowded into the cervix. The vagina was very tightly packed. This was not done however until the uterus had returned to its small size below the symphisis pubis.

It perfectly controlled the hæmorrhage. The sighing and alarm of the patient had returned. She was tossing from side to side. Enemas and subcutaneous injections were given. The heaters were renewed and placed about the patient. The pulse at the wrist was rapid in the extreme, and at times could not be felt. For three-quarters of an hour every effort was made to improve the patient's condition, but she grew steadily weaker. The skin was cold and clammy. The pupils were widely dilated. The patient's mind wandered. Death was imminent. As a last resort it was decided to attempt a second infusion. The left median cephalic vein was this time opened. Thirty ounces of the salt solution were added to the circulation in forty minutes. Slowly the pulse appeared at the wrist. It then became constant, though rapid and feeble. The patient soon became quiet but was utterly exhausted. The pulse ranged between 150 and 160 and could only be accurately counted at the chest. Six hours later the pulse had fallen to 148, and was somewhat stronger In twelve hours it dropped to 140. Here it remained, for thirty-six hours, when it fell to 130. On the three following days it ranged between 120 and 130.

February 12. Nearly a week has elapsed, and the patient is doing well. The prognosis is favorable.

February 13. The patient had a chill and the temperature rose to 105°. She was seen by Dr. W. L. Richardson in consultation. He gave a favorable prognosis.

REMARKS.

The cause of the first hæmorrhage was an ante-partum separation of the placenta, brought about perhaps by lifting or by old endometritis or by a combination of the two causes.

The cause of the second hæmorrhage was a relaxation of the uterus occurring an hour and a half after the birth of the child.

The labor may be divided as follows:

February 6th.	5. P.M.	First pains.
	5.30 "	A flow of blood.
	9.45 "	A second large loss of blood.
	10.10 "	Ether.
	11.00 "	Child born.
	11.45 "	First infusion begun.
February 7th.	12.10 A.M.	First infusion finished.
	12.45 "	Post-partum hæmorrhage.
	1.30 "	Second infusion begun.
	2.10 "	Second infusion finished.

Since the labor the stomach has acted well. There has been excessive thirst but no appetite. She has been given liquid foods and stimulants in small quantities at short intervals.

No urine was drawn for eighteen hours after the birth of the child. Then two ounces were removed by the catheter. The amount secreted soon increased.

An analysis of the urine by Dr. Charles Harrington gave the following result, February 8.

Color=sl. pale.	Sp. Gr.=1,016.5.
React.=acid.	Amount of Sediment=slt.
Uropheïn=N.	Chlorides=M—.
Indican=M+.	Sulphates=N.
Urea=Normal.	E. Phosphates=M—.
Albumen=trace.	Alk. Phosph=+.

Sediment=Free blood and a few hyaline casts.
Amount of NA. CL.=0.04 per cent. or 0.400 gm. per litre.

Instead of an increase of the chloride of sodium, we find it almost absent, the normal amount being from seven to eleven grms. per litre.

Four days later the amount of salt in the urine had more than doubled. The packing was removed from the vagina without much difficulty on February 9th. No hæmorrhage followed. The respiration has remained at a low rate, ranging from ten to twelve for four days.

The stitches were removed from the arms on the fifth day. There had been union by first intention in both.

A specimen of the patient's blood examined in regard to its richness in red corpuscles showed that there had been a diminution from 4,500,000 to 1,838,000 per c. m. m. On the 12th there was a farther decrease to 1,824,000, and on the 13th to 1,658,000. This apparent decrease may have been due to the absorption of water by the blood, at a more rapid rate than new corpuscles could be formed. The number of white corpuscles was largely increased.

The breasts have remained perfectly soft and no milk could be pressed from them.

The subject of the infusion of salt solution was first brought to the notice of the writer, by a paper "On the Value of Transfusion of Blood and Infusion of Salt Solution in Acute Anæmia," which was read by Dr. O. K. Newell on April 1st, 1885, before the Surgical Section of the Suffolk District Society, and which unfortunately has never been published. The paper was a translation of an article by Professor Mikulicz (Ueber die Bedeutung der Bluttransfusion und Kochsalzinfusion bei akuter Anämie. Weiner Klinik, Juli 1884.

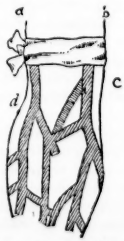
Mikulicz advises a solution made as follows:

Sod. Chloride	6 0=3 iss
Sod. Bicarb	1 0=grs. xv
Aq. Distillat	1000 0=oii+

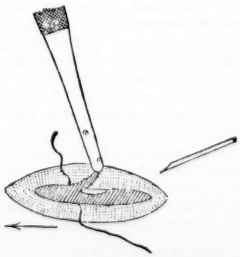
This should be raised to about 100° Fah.

From a pint to three pints can be used. The utmost care should be used that no air shall enter the circulation.

The median cephalic vein can be most conveniently used. The vein should be dissected out and the needle tied into it.



Cut I. Superficial Veins at Bend of Elbow: *a*, outside; *b*, inside: *c*, basilic vein; *d*, cephalic vein.



Cut II. Method of inserting needle.

Cut III. The needle in position. The arrow indicates the direction of the current.

The amount of pressure can be regulated by raising or depressing the reservoir. The solution enters the current quickly at an elevation of three feet.

The apparatus used on this occasion was such as could be hastily adapted from the ordinary office instruments: a large needle from an aspirating set, with a piece of drainage tube and a small glass funnel.

As to the benefit of the salt infusion in this case there cannot be a shadow of doubt. The relief given was as apparent as from tracheotomy in diphtheria.

The salt infusion was not tried until all other means had failed. Should the patient die it has given a week of life and hope.

February 28th. The patient is doing well. The prognosis is favorable.

There was progressive anæmia until Feb. 18th when the red corpuscles had diminished to 1,180,000. After this time they began to increase, and on Feb. 28th reached 2,040,000 per c. m. m.

REPORT ON RECENT PROGRESS IN THORACIC DISEASE.

BY F. C. SHATTUCK, M.D.

CONSEQUENCES OF NARROWING OF THE MITRAL VALVE WHEN OCCURRING IN CHILDHOOD.

The following is a portion of a short article by Dr. Wilks.[1]

"In various ways the effects of heart disease are different as occurring in the growing child and adult. After a marked endocarditis in the child, resulting in thickening and narrowing of the mitral valve, there may be observed great enlargement of the left auricle, with hypertrophy of the right side, becoming sometimes so great as to cause bulging of the chest. In these cases the pulmonary artery partakes of the hypertrophy of the ventricle, and is often found thicker than the aorta. Many years ago, when demonstrating this condition, I used to teach that in all probability the second sound of the heart was produced more by the pulmonary than by the aortic sigmoid valves, and this was before I became aware of the clinical fact pointed out by Skoda that the second sound was more accentuated over the pulmonary orifice in mitral disease. But in cases where there has been no history of endocarditis, although it might probably at one time have been present, where the valves have become contracted without much thickening, and therefore retained their efficiency, these secondary effects do not and need not occur. It is evident that the whole of the blood of the body coming back to the lungs and then passing again to the left side, is measured by the size of the mitral orifice. If this be small, the blood passing through it is diminished in quantity and it becomes a guage of the reduced circulation. The left ventricle is therefore small, and the whole heart correspondingly diminished in size. The lungs are small as well as the chest, and the respiratory process correspondingly lowered, and with this, probably the whole body is impoverished; at all events, the organism is working with a diminished amount of blood. I admit that these simple cases of narrowing are exceptional, for most frequently with the contraction there is some thickening which in course of years manifests itself by symptoms denoting an imperfection of the valve.

"It is, however, the exceptional cases to which I wish to draw attention, those in which the mitral orifice, when narrowed, acts first by producing a diminished stream of blood, the amount in the system being measured by the small mitral orifice, and then, as before said, by a shrinking of the other parts of the circulatory system. During the present year I have seen two such cases on the *post-mortem* table. One was that of a woman of middle age who had died of some long-standing disease of the brain. In her body was found a very small mitral aperture, admitting only the point of the finger, but having its edges pliable and in every way efficient as a valve. The ventricle was very small and the whole heart was diminished in size, proving that no obstruction or regurgitation had occurred in the mitral orifice. The lungs were not indurated, nor did they show in any way the congestive conditions so well known in heart disease when the blood has been impeded in its course, nor did the other organs display any indication whatever of analogous congestive processes. A very intelligent student expressed his surprise at the absence of the well recognized conditions usually met with in obstructive mitral and other valvular diseases, and that there was not the slightest appearance in the body suggestive of stenosis of the valves of the heart. My answer to him was that there was no disease; the mitral orifice was smaller than natural, but an effective valve. The contraction had no doubt occurred at an early period of life, and so reduced the amount of blood, of which it was the guage; that the whole heart became in consequence reduced in size, and an entirely new state of things set up. This condition is very different from what occurs when a person is full grown and becomes the subject of a stenosed mitral valve, but even then the prolongation of life is due probably in some measure to the reduced amount of blood in the system."

DROPSY IN MITRAL STENOSIS.[2]

Dr. Broadbent in the course of an admirable article on mitral stenosis remarks on and explains the relative infrequency of dropsy in the above condition. He says: "Another fact which has been impressed upon me, in the course of my observation of the various forms of heart disease, is the late stage at which general dropsy supervenes in uncomplicated mitral stenosis. Not unfrequently the subjects of it are free from œdema at the moment of death, and very commonly it is absent when the symptoms arising from the condition of the heart are most urgent; it may set in suddenly after these have lasted for some time. Ascites, again, may occasionally be present independently of œdema, or it may persist after œdema has subsided, occurrences which are altogether exceptional, if not unknown in other forms of heart disease. When dropsy comes on comparatively early, regurgitation will usually be found as well as obstruction, and the incompetence of the valve may not improbably play a greater part in the production of the symptoms than narrowing of the orifice."

[1] Lancet, 1886, 1, 6.

[2] American Journal of the Medical Sciences, 1886, 1. p. 57.

I have met with an extreme degree of dropsy only when there has been tricuspid stenosis, as a complication by the initial stenosis, and have come, in the diagnosis of this complication, which in most cases does not reveal itself by separate physical signs, to rely upon blueness and lividity of the countenance, and to waterlogging of the tissues and cavities.

The seeming capriciousness of dropsy in heart disease long ago forcibly struck Walshe and led him to the conclusion that there is some active cause beyond and independent of the heart, something beyond and in addition to any one or any group of cardiac lesions which is required for the production of the dropsy. What this active cause is, Walshe does not state; but he dwells upon changes in the blood, in the vessel walls, and in the tissues themselves, as factors in the production of dropsy. Broadbent, on the other hand, believes it unnecessary to seek for any active cause outside of the heart, and thinks that Walshe and others who share his views, have fallen into error by allowing to simple venous stasis and consequent slowing of the circulation through the capillaries too prominent a rôle. He says: "But it is not a question merely of obstruction in the veins, but of pressure in the capillaries, and if *vis a tergo* in the arteries is wanting, the condition under which the exudation takes place does not arise. Of course, whenever the resistance to the return of blood to the heart is such that the pressure in the arteries is unable to overcome it, actual arrest of the onward movement of blood in the capillaries occurs, and life ceases at once; but, short of this, and subject to the production of the degree of intravascular pressure needed to keep up the nutricent overflow into the intertextural space, the movement of blood in the capillaries may be very languid. Given a retarded circulation through the capillaries produced by venous obstruction, the occurrence of dropsy will depend on the pressure of blood in the arteries, and in mitral stenosis the conditions are such as to forbid any augmentation of it. Followed to its source, the pressure in the circulation depends, ultimately, on the left ventricle. Increased resistance in the capillaries is met by the increase of strength and vigor given by hypertrophy, and when disease affects its outlet, compensation is obtained by hypertrophy with or without dilatation.

"Under certain conditions the left is reinforced by the right ventricle, under all conditions, in fact, in which the pressure in the pulmonary circulation is increased and the right ventricle is hypertrophied, except when such augmented pressure is intercepted by a narrowed mitral orifice. But in mitral stenosis the left ventricle is not hypertrophied, and, in consequence of the narrowing of the orifice, can get no help from the right, beyond such as is afforded by the more efficient filling of its cavity. The amount of blood entering it is, in advanced cases, probably less than normal, notwithstanding the increased pressure in the pulmonary circulation, and can scarcely at any time exceed the normal. It is not, however, propelled into the arteries with increased force. Although the veins there may be full, and there may be every appearance of backward pressure in the capillaries, the real source of pressure in the capillaries is wanting."

A NEW PHYSICAL SIGN OF TRICUSPID REGURGITATION.

"This sign consists in a distension, with or without pulsation, of the superficial veins of the neck, occurring when firm pressure is exerted over the liver in the direction of the spinal column, and independent of the movements of respiration. A little consideration of the anatomical relation of the parts concerned will suggest the facility with which an impediment may be created to the flow of blood, in either direction, through the vena cava inferior by such a manœuvre, especially when the liver is obviously enlarged. It seems to me that the state thus produced is virtually that which obtains as a chronic condition in long-standing and severe cases of tricuspid incompetence as far as regards the tension in the systemic venous system in the immediate vicinity of the heart. Assuming the existence of tricuspid regurgitation and of a source of compression of the vena cava inferior, it is obvious that with each systole an excessive reflex of blood must take place into the vena cava superior and its tributary veins. It may be noted that the question of pulsation as compared with pulsation or undulation, is merely one of degree of morbid venous tension. Although the number of cases in which I have observed this phenomenon is certainly limited, I have never failed to elicit it when there was indubitable evidence of tricuspid incompetence; on the other hand, I have hitherto invariably failed to obtain it in other forms of cardiac valvular disease, and in various cases of hepatic enlargement from causes other than passive congestions."

NEW HEART TONICS.

Spareine sulphate has been used with good effect by Sée,[3] who thinks its influence is more prompt and more enduring than that of digitalis. The base of the salt is derived from a variety of broom tops and, in combination with sulphuric acid, is quite soluble in water. The dose is ten centigrammes. "When the pulse is irregular, intermittent, and arythmic, sulphate of spareine rapidly re-establishes the normal type. When the circulation is slackened the drug seems promptly to oppose this functional trouble, while maintaining or even increasing the acquired force of the cardiac muscle."

[The drug can be had in this country but must come down in price before it can be much used. The present price to physicians is one dollar a gramme. The reporter has used it in two cases and knows of several others; in these the results were inconclusive.]

Strophanthin receives especial attention from Prof. Fraser in an article on the digitalis group.[4] Strophanthus is an African arrow poison, and Fraser has extracted from the seeds of the plant a crystalline body readily soluble in water and in rectified spirit; this he calls strophanthin. However introduced into the body this substance increases the contractile power of all striped muscles, and renders their contractions more complete and prolonged. The heart is early and powerfully affected, and by regulating the dose a distinct influence may be produced on the heart, while the other muscles are apparently unaffected. At the same time the blood pressure rises and in certain conditions the urine is increased and the temperature lowered. These facts led to the use of the drug in a large number of cases in which digitalis or its equivalent was indicated, and with most encouraging results. Further experiments on animals, digitalin and strophanthin being compared, lead Fraser to think that the latter

[3] Gazette Médicale de Paris, Nov. 28, 1885. Boston Medical and Surgical Journal, 1885, II, p. 599.
[4] British Medical Journal, 1885, II, p. 904.

exerts a much more powerful action on the heart and a less powerful action on the blood-vessels than the former. While he is not prepared to say what the exact significance to therapeutics of this difference may be, the advantage seems to lie with strophanthin in the treatment of cardiac disease. "In difficulties and embarrassments of the circulation depending on a central cause, it seems preferable to act upon the heart alone, rather than also to increase its difficulties by closing the blood-vessel into which it must empty itself."

Speaking of the digitalis group generally, Prof. Fraser says: "I regard, in common with many others, the characterizing action of the members of the group to be the action on the heart. They may be used with advantage in all weak states of this organ, whatever the cause of weakness, and their most satisfactory results are, I think, produced in mitral disease.

"They do little, if any, good when the cardiac muscle has undergone much degeneration; they sometimes fail, even while degeneration is absent, when lesions of the orifices throw too great a burden on the heart, and they are injurious when sufficient compensatory changes have been produced." In most of the cases the strophanthus was used in the form of a tincture prepared with the quantities prescribed in the British Pharmacopœia for tincture of digitalis. The dose is not definitely stated. Of the strophanthin the hypodermic dose seems to be grain 1-60. It should be added that Prof. Fraser's studies of this remedy have been going on now for fifteen years.

The drug is not yet to be had in this city, but a small quantity is on its way to T. Metcalf & Co.

THE ORIGIN AND DIAGNOSTIC IMPORT OF DILATED CUTANEOUS VESSELS NEAR THE LOWER BORDER OF THE LUNGS.

Sahli[5] has noticed this change especially in sufferers from chronic cough, and has often seen combined with it a line of minute ectatic vessels coinciding with the limits of the cardiac dulness. The explanation lies in the increased intrathoracic pressure resulting from the cough; the internal mammary and intercostal veins are compressed by the lungs and thus stasis is caused in the superficial cutaneous veins in the above situation. The cough persisting, gradually the vessels become permanently dilated.

Although the course of the line of dilated veins does not correspond exactly with the lower border of the lungs an unusually low situation of the line indicates a lowered position of the pulmonary border. This point enabled Sahli to diagnosticate emphysema in a case where the condition was quite masked by dropsical effusion. He thinks the presence of this line of dilated vessels may be taken as a safe indication of long standing cough.

TRAUMATIC PHTHISIS.

Mendelsohn[6] calls attention to a class of cases which seems to have escaped the attention of most writers on thoracic diseases with the exception of Lebert,[7] who says: "Traumatism is far from being rare as a cause of phthisis and one is justly surprised that the connection has attracted so feebly the attention of physicians." A few cases have been reported here and there in the journals; these Mendelsohn has collected, and adds to them nine cases from his own experience, in eight of which no hereditary tendency to the disease could be traced. The injuries were of different kinds and degrees of severity; in some there was no positive evidence of anything more than a severe shaking up or compression of the lungs; in others there was hæmoptysis, but this symptom may be absent although the lung tissue is more or less lacerated and the amount of blood expectorated is no reliable indication of the amount poured out into the fine structure of the organ. The tearing of the tissue, the bleeding, and inflammation with its accompanying hyperæmia, all favor the lodgment and growth of the tubercular bacillus. In ordinary phthisis the apex is the favorite seat for the commencement of the process because it is that portion of the lung which is ventilated with the greatest difficulty, and it seems highly probable that in these traumatic cases the limitation of movement dependent on the pain acts in a similar manner.

SÉE ON THE TREATMENT OF ASTHMA BY PYRIDINE.[8]

This colorless and strong-scented fluid is obtained from many organic substances by dry distillation. It has been detected in nicotine and other alkaloids and in the fumes of tobacco. It is probably the active principle of the various cigarettes and papers which have been recommended against asthma. Recent experiments by MM. Sée and Bochefontaine have shown (Bull. Géner. de Thérap., June 30) that it produces in frogs and guinea pigs a diminution of the irritability of the respiratory centre. Pyridine has been tried in asthma with marked success; four or five grammes of this fluid are poured on a plate and placed in a small room in which the patient remains for from twenty to thirty minutes, three times a day. The respiration becomes easy, and after a few sittings the disease disappears more or less completely. The inhalations have no bad effect on the heart or general health. In spite of these good results, M. Sée still considers iodine the best curative remedy in asthma; pyridine is chiefly useful against the attacks of dyspnœa.

TEREBENE IN CHRONIC BRONCHITIS.[9]

During the last five years Dr. Murrell has used this remedy with excellent results in cases of winter cough, having notes of 114 cases. The drug is prepared by the action of sulphuric acid on oil of turpentine and is not to be comfounded with a patent medicine sold under the name "Tereblene." It is pleasant to take, being a clear colorless liquid with an odor like that of fresh-sawn pine wood; it will not mix with water but can be taken on sugar. The dose is m. x–xxx every four hours, but it can also be atomized and inhaled. Larger doses are well tolerated, and the only disadvantage noticed from its employment is the peculiar odor it imparts to the urine, a circumstance patients never fail to mention. A case is reported which is said to be fairly typical of all, and certainly speaks well for the efficacy of the remedy.

— The *Union Pharmaceutique* states that, in a perfectly serious advertisement, a French oyster dealer offers for sale both ferruginous oysters and tar oysters.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

F. M. BUCKINGHAM, M.D., SECRETARY.

February 22, 1886, the President, Dr. F. W. Draper, in the Chair.

POLYPUS RESEMBLING INVERTED UTERUS.

Dr. Minot reported the case, and showed the specimen, the chief interest of which lay in the diagnosis. The patient, a widow thirty-four years old, applied at the out patient department of the Massachusetts General Hospital, under the care of Dr. F. B. Harrington, stating that she had had a miscarriage four years ago, and no pregnancy since. During a year past she had had much pain in the back and pelvis, with frequent hæmorrhage. In September last she noticed a lump in the vagina, which afterward increased in size and then "went back." Three weeks ago, while lifting a heavy kettle, she felt something give way in the pelvis, was immediately seized with hæmorrhage, which had continued more or less profusely afterward, and found that the tumor had again descended into the vagina. As the diagnosis was uncertain, Dr. Harrington asked Dr. Minot to examine the patient with him. There was a firm fleshy mass in the vagina, of about the size and shape of the uterus. Its surface was uneven, of a dark color, and covered with blood, which flowed freely during the examination. The tumor seemed to be connected with the interior of the uterus, but the sound could not be made to pass between it and the uterine walls into the cavity. A sound in the bladder could be felt by the finger in the rectum.

On account of the restlessness of the patient from pain, the examination was not satisfactory; and it was decided that she should enter the hospital for a more careful one and for treatment. On the following day, the patient being etherized, it was found that the pedicle of the tumor was attached to the interior of the cervix, almost completely around, so that the finger could not pass beside it into the cavity of the uterus. After some search a passage was found into which the sound easily entered to a distance of two and a half inches in the downward and backward direction. The openings of the fallopian tubes were sought for, but could not be found. To make sure, a small portion of the mass was excised, which showed the appearance of the ordinary fibroid growth. The mass was then drawn down and cut off with scissors. There was no hæmorrhage of consequence, either at the time of the operation or since, and the woman has done well. The retroflexion explained the facility with which the catheter in the bladder could be felt in the rectum, as it passed directly over the uterus, thus adding to the embarrassment in the diagnosis.

It might be said that uterine inversion was impossible with the history of the case; but it was not thought justifiable to base a diagnosis, which might cost the woman her life if incorrect, upon her statements, since she might have some motive for concealing the real facts of the case.

Dr. Franklin H. Hooper read a paper on

ADENOID VEGETATIONS IN THE NASO-PHARYNGEAL CAVITY.[1]

Dr. Knight, who, unfortunately, was unable to be present, sent the following notes to be read by the secretary:

"I regret exceedingly to miss the reading of Dr. Hooper's paper, and not being able to open the discussion as you very kindly asked me to do.

"I well remember bringing up the subject of adenoid hypertrophy at the pharyngeal vault many years ago, when it first began to attract attention, in our old quarters in Temple Place. Some of the gentlemen present may remember the excited manner in which the late professor of pathological anatomy denied that there was any adenoid tissue at the vault of the pharynx, and how, having a good dissection on hand, I convinced him of its existence.

"A little later I was asked by a distinguished surgeon to examine with the posterior rhinoscope a young lady on whom he, a few days before, had performed tracheotomy, preliminary to the bloody operation of resection of the superior maxilla for naso-pharyngeal polypus. The gentleman confided to me with some anxiety that the tumor was not nearly so prominent as it had been. I found a moderate adenoid hypertrophy, which had probably been acutely swollen, and led to the erroneous diagnosis of naso-pharyngeal fibroid. The patient was discharged 'much relieved'!

"As we know it at the present day, this adenoid is capable of enormous hypertrophy, so that nasal respiration is completely occluded.

"In regard to its treatment, there is, I imagine, little difference of opinion about the necessity of removal, when it is sufficiently large to seriously obstruct nasal respiration, to seriously impair the voice, or threaten the hearing. To accomplish this, I have used the cutting forceps more than any other instrument, though I have occasionally removed large pendulous masses by means of the wire snare passed through the nose.

"I have shared the prejudice against the sharp spoons of various kinds which have been recommended for this operation, but the perusal of Trautmann's recent monograph, including detailed accounts of one hundred and fifty cases, makes me think that the operation may be done much more expeditiously with such a spoon as he recommends. He uses a large very sharp spoon, which is passed under the soft palate up towards the septum, and then made to cut across towards the posterior wall of the pharynx, getting out much larger masses than with the forceps. I attach some importance also to the fact that Trautmann was familiar with and used the cutting forceps before adopting the spoon.

"Shall the operation with forceps be done under the guidance of the rhinoscopic mirror? Certainly, if that is possible, but I can but think that the dictum in a recent treatise that forceps should never be introduced into the post-nasal region except under guidance of the rhinoscopic mirror is unnecessary. In many cases, on account of the age of the patient or irritability of the fauces, the mirror cannot be used at all. In using the forceps or any instrument in the posterior nares by the sense of touch alone, I think our efforts should be directed to clearing away the central mass which blocks nasal respirations and avoiding the lateral regions of the Eustachian orifices.

"In the cases of unmanageable children, it seems to me most satisfactory to resort to etherization at once. For an operation under an anæsthetic, the forceps is the best instrument, as, tearing off bits at a time, the

[1] See page 193 of this Journal.

hæmorrhage is usually trifling, and can be regulated, whereas, with an instrument making a large cut surface, the bleeding is sometimes profuse, and it might be hard to keep the blood out of the larynx."

DR. LANGMAID said that almost nothing could be added to the very interesting and complete paper which Dr. Hooper had read. He could not agree with the theory that the disease was congenital. He believed that it was generally the result of scarlet fever or measles. The physiognomy of the mouth-breathing child had been so graphically described that it might be well to refer to another characteristic which had not been mentioned, namely, the inhibitory effect upon respiration, which is almost always produced in severe cases. When the child is sleeping, the respiratory act is so interrupted that an interval of twenty seconds or more will elapse after an expiration before the delayed inspiration takes place. This is accompanied by, or rather, consists in a loud snort. This laborious and interrupted breathing is not unfrequently the cause of great anxiety to the child's attendants, who are in constant dread lest the breathing cease forever. In more than one instance the mother's health has been seriously impaired by long-continued night vigilence. No one need ever be in doubt as to the cause of such interrupted respiration in a young person.

Dr. Langmaid considered the method of making a diagnosis by means of the finger extremely fallacious. A rhinoscopic examination was not only desirable for diagnosis, but also for proper treatment. The time had long passed when the knowledge to be obtained by thrusting the finger into the naso-pharynx could be considered in any way equivalent to the exact information which the rhinoscopic mirror affords.

DR. J. O. GREEN said that when this adenoid growth closes the orifices of the Eustachian tube it prevents the ventilation of the tympanic cavity and in this way may produce various forms of inflammation; or inflammation may, also, by a mere process of extension from the original growths, reach into the Eustachian tube. A third ear complication may in his opinion be a small celled infiltration of the sub-mucous tissue, which infiltration becoming organized causes permanent thickening. Here the question of heredity comes up, and it is true that in some of the worst cases no such results follow. Nevertheless he is certain that he has seen cases in which it did follow.

The readiness with which the Eustachian tube when closed by these growths may sometimes be opened is sometimes striking, and it may then stay open. On the other hand even small growths may close it so that it closes again after inflation.

DR. C. J. BLAKE said that depression of the membrana tympani, with congestion of the mucous membrane and deafness are sometimes found in connection with these growths. He mentioned the case of a deaf patient, a mouth-breather with an adenoid growth in the naso-pharynx; inflation was not successful, but on removal of the growths, hearing became five times as good in one ear and more than twice as good in the other, and then after a few inflations soon became normal.

DR. FARLOW said that the expression of the mouth-breather is something very marked, as described by the reader. Patients so afflicted are often brought to the Dispensary rather for relief to the expression than on account of the breathing,

DR. J. O. GREEN said that emphasis ought to be laid on the tendency of these growths to shrivel after puberty. He mentioned a family in which all the sons were mouth-breathers in boyhood and all gradually recovered.

APPOINTMENT OF MEDICAL EXAMINERS BY THE STATE.

DR. CHAS. D. HOMANS, Chairman, stated that the committee appointed Nov. 23d to consider the above subject was ready with its report. The report, which follows, was read by Dr. Fitz, and was unanimously accepted.

REPORT OF THE COMMITTEE OF THE MEDICAL IMPROVEMENT SOCIETY ON MEDICAL EXAMINERS IN MASSACHUSETTS.

To the Boston Society of Medical Improvement:

THE undersigned, your committee appointed Nov. 23, 1885, to consider the subject of medical examiners in Massachusetts, respectfully report as follows:

The law concerning medical examiners was passed in 1877, and under its provisions there are at present seventy-two incumbents. These must be "able and discreet men, learned in the science of medicine." Seven years later Dr. F. H. Brown states (Medical Register for New England) that "since its introduction in 1877, about 9,000 cases of violent, sudden and suspicious death have been investigated in a satisfactory manner in Massachusetts, without any complaint from any one as to the abolition of the coroner and his jury."

A year ago the Governor of the Commonwealth found it necessary to make, in his inaugural address, the first public criticism of the working of the law. Admitting that on the whole it was satisfactory, he called attention to the possibility of its abuse in cases of railroad accident by permitting unnecessary autopsies with a correspondingly increased charge to the county or State. He gave an instance of such abuse, and recommended that a report of all autopsies should be made to the district attorneys, and that the examiners should "make oath in each case that in their judgment the cause and manner of death could not be ascertained by view and inquiry, and that an autopsy was fairly necessary for that purpose." Fees for autopsies were not to be paid except with the approval of the district attorney who was to examine the report and certify whether the autopsy was required. The governor also suggested the probable necessity of other amendments which should define certain words and clauses, fix the rate of fees, and otherwise make clear the intent of the statute.

The making of unnecessary autopsies with or without increased cost to the State, may be regarded as an indiscreet act at least, though not necessarily dishonest, and the medical examiner must be discreet. Your committee have been informed that the officer above referred to was removed.

It is to be regretted that the attention of his excellency was not at the same time directed to the apparently unnecessary extravagance of double inquests in fatal railroad accidents. The statutes not only require that the railroad commissioners shall investigate the causes of such occurrences, but that it shall be the duty of the medical examiner also to initiate a judicial inquest. The necessary legislation would thus have prevented a recognized abuse of official power and at the same time have caused an additional saving of the public funds.

The second public criticism comes from a medical source in the paper read before your body by Dr. W. C. B. Fifield. The question is raised by him "whether or not the time has come when the present system of medical examiners as appointed by the State ought to perish and give place to something better."

The main objections to the existing law as stated by the reader, relate to the method of appointment, and to the insufficiency of the payments for the services rendered. The former is claimed to be faulty since it results in the selection of incompetent officials and the use of unworthy means in obtaining the position. No facts are given as evidence of the insufficiency of the fees but it is obvious that incompetent incumbents easily earn their wages, and competent examiners, as represented by the Medico-Legal Society, have lately obtained a desired increase of fees.

Although a single instance is given of the payment of an agent for assistance in securing an appointment it is presumable that the appointee had other qualifications than those of a pecuniary nature. This fact does not strengthen the argument against the appointing power, as it is hardly probable that the sum was spent in bribery. As the instance referred to was published in the courts, the attention of the governor and council could readily have been directed to the transaction.

The value of an agent's services must be so limited that no action is recommended which shall guard against the possibility of his employment.

Your committee recognize the merits of the reader's definition of competency in medical examiners, and desire with him that "they should be in every instance well-bred and well instructed gentlemen, competent from education and professional training to fill this very responsible post, not to be entered into carelessly and thoughtlessly, but soberly and seriously, well weighing its many obligations; able to make an exhaustive *post-mortem*, with full knowledge of what will be demanded by the law; possessed of sufficient knowledge of chemistry and toxicology to recognize the *post-mortem* appearances produced by ordinary poisons and to determine their presence by chemical analysis."

They agree that the medical examiners in general have not attained, this standard but they cannot admit that a rigid practical examination of each candidate would secure such officers. On the contrary, if the examination could be made sufficiently severe to guarantee the desired result, it might well be questioned whether enough appointees could be obtained to serve the interests of the State.

As the medical examiners have now for the first time been publicly charged with incompetency, your committee have thought it of the highest importance to ascertain to what extent this accusation was justified. To form an opinion on this point they have considered *seriatim* the instances mentioned by the reader, have consulted the manuscript reports collected by the Medico-Legal Society, and have sought for information from the several district attorneys.

Six instances are mentioned in the paper presented to your Society.

First. The experience of the district attorney who refused, in the latter years of his practice, to present to the grand jury a case seen by the medical examiner unless it had first been submitted to an expert's guidance, with the view of securing at a *post-mortem* examination valuable evidence which might otherwise have been overlooked.

Your committee are of the opinion that the law does not require that the medical examiner should necessarily be an expert anatomist, and the above instance shows that the district attorney recognized this fact.

Second. An examiner neglected to obtain the negative evidence necessary to control the argument for the defence.

An error of omission which might have been obviated had the government secured the early assistance of an expert. The error of location in the indictment does not suggest medical incompetency, and the plain statement of the fact does not permit its author to be recognized.

Third. A medical examiner failed to secure suitable evidence of the manner of death. The examiner first called contented himself with a view, presumably unaware that the suspicion of murder was to arise. His diagnosis of death from disease of the heart was in accordance with a customary formula, the use of which is objectionable but likely to be retained while it is the policy of the State to discourage apparently unnecessary *post-mortem* examinations. The second examiner falsified a fact in stating the existence of what proved to be absent, and was incompetent as not showing a familiarity with an important branch of the science of medicine.

Fourth. A medical examiner was satisfied with the view of a dead body in the absence of information suggesting death from violence. This information would have been obtained had the law required an autopsy in all such cases, but Section 8 of the law reads as follows: "Whenever a medical examiner has notice that there has been found, or is lying within his county, the dead body of a person who is supposed to have come to his death by violence, he shall forthwith repair to the place where such body lies and take charge of the same; and if on view thereof and personal inquiry into the cause and manner of the death, he deems a further examination necessary, he shall . . . make an autopsy, etc."

Your committee cannot recognize the above as an instance of incompetency, even if it be admitted as one of negligence. The supposition of death from violence appears not to have arisen till some days after the view of the body, and the law is incomplete in not clearly defining what is meant by a view.

Fifth. A doubtful diagnosis. The anatomical evidences of typhoid fever and cerebro-spinal meningitis being usually sufficiently characteristic, the examiner must be deemed incompetent who makes a diagnosis of the latter affection from the inspection of the dura mater after a simple removal of a part of the lumbar vertebræ.

Sixth. Dissatisfaction of the jury with the medical evidence. That a jury finds death to have been caused by some unknown means, despite the medical evidence, is no proof of incompetency on the part of the examiner. If a district attorney and the examiner assisted by four experts, cannot convince twelve average men that five mortal wounds are fatal, your committee find no occasion to charge the medical examiner with incompetency.

The above detailed consideration of the instances cited by the reader leads to the conclusion that the errors of medical examiners are rather those of omission than commission, and in two instances are more the fault of the law than of the examiner. Two examples of actual incompetency are presented.

The medical examiner cannot be deemed incompe-

tent if innocent persons are arrested and imprisoned. If he suspects a death to result from homicidal violence he is not called upon to direct his suspicions towards individuals. The judicial officer, not the medical examiner, causes arrests and the former, not the latter, is to blame for unjust imprisonment.

The Massachusetts Medico-Legal Society includes in its membership a majority of the medical examiners in the State. During the first five years of its existence, beginning in 1877, an attempt was made by its secretary, Dr. F. Winsor, to collect and preserve full and detailed reports of the medico-legal work of its members. Eleven volumes of these manuscripts are deposited with the Boston Medical Library Association. Your committee have examined a sufficient number of these records to enable them to form a satisfactory opinion of the nature of the work done by the members of the Society in the years represented. The contributions were voluntary and obviously come from those members most interested in their work and obligations. It appears from the inspection of the reports of autopsies that there was no agreement as to the form and fulness of these records. Some are well-proportioned, clear and objective statements of facts, arranged in proper sequence and logically justifying the final opinion of the cause and manner of death. Others are unsatisfactory as failing to present all the evidence necessary to justify the conclusion. In a few, faults of omission are conspicuous and methods of statement are inaccurate.

The importance of obtaining the opinion of the prosecuting officers as to the competency of medical examiners is apparent. As your committee were appointed in somewhat indefinite though very comprehensive terms, to report upon the whole subject, they addressed a circular letter to each of the eight district attorneys of the State. Information was sought as to the competency of the examiner, the satisfactory nature of his work, the feasibility of reducing the number, and the least number necessary for the timely performance of the duties. A reply to this circular was received from each of the officials addressed, and your committee take this opportunity of expressing their obligation for the willing, comprehensive and suggestive answers.

One medical examiner was found incompetent, and it is not unlikely that he was one of the two referred to in Dr. Fifield's paper. The errors of certain examiners were as often due to defects of the system as to those in the examiner. Two were regarded as unduly zealous in making autopsies. In no instance, however, was there any delay or failure of justice in consequence of unsatisfactory work on the part of the medical examiner.

The evidence thus attained from various sources goes to show that among the seventy-two medical examiners two, at the most three, had been recognized as incompetent, yet their incompetency has not caused a delay or failure of justice. A considerable difference in the ability, discretion and learning of the several examiners undoubtedly exists and is likely to continue, whatever change might be made in the method of appointment. Errors of omission and obscurity of statement occur, but these are faults which can be very considerably diminished.

The existing law offers a simple and rapid method of disposing of incompetent examiners. Section 4 provides that they "Shall be liable to removal from office at any time by the governor and council for cause shown." All the prosecuting officers of the commonwealth, the mayors of cities, the selectmen of towns, the commissioners and treasurers of counties, are immediately interested in the accuracy, thoroughness and honesty of the work of the medical examiners. Any or all of these officials would be compelled to show an existing cause for removal, if for no other reason than to relieve themselves from a possible urgent public criticism.

With the recognition of the desirability of more nearly approaching the ideal standard of the medical examiners as raised by the reader of the paper, the question arises as to the means to be employed which may bring about this result.

Dr. Fifield suggests that the law be amended by the appointment of an examining committee to nominate candidates, or that the latter present certificates of proficiency from teachers of medical jurisprudence. How shall the examining committee be appointed and of whom shall it be composed? The evils of the existing law must be extreme before so radical an amendment could be adopted, and then the possibility of even worse evils is manifest. A board representing the several medical interests of the State, especially with members selected through political influences, would be in danger of recommending candidates whose action might prove criminal as well as ignorant. The Utopian nature of this proposition is admitted by its advocate.

If all the medical schools of the country were of the same high character, and in each a thoroughly qualified teacher of medical jurisprudence gave instruction with abundant opportunities for illustration, certificates from the latter might possess a certain practical value. The relative merits of candidates, however, cannot be determined by means of certificates of proficiency from different sources. Furthermore, the appointing power should demand evidence of other qualifications in a candidate than his ability to answer certain questions in a becoming manner.

Your committee are therefore of the opinion that any feasible change in the method of appointing medical examiners is not sure to improve their quality.

It seems, however, that the public welfare, so far as it depends upon the work of the medical examiner, might be decidedly promoted were a smaller number of more highly qualified persons selected for this office. A suitable salary as well as the dignity of the position would enable the services of the most desirable to be secured, and these would become all the more competent from the more frequent opportunities of investigation furnished each. A recommendation tending to bring about such a change is not made since the work of the examiners, almost without exception, is at present satisfactory to the prosecuting officers and causes no delay or failure of justice. Although certain of the district attorneys admit the possibility of more efficient work from a smaller number of examiners, the expediency of the change is questioned. Should the time arrive when the expediency is generally admitted, your committee are strongly of the opinion that the suggested modification would be productive of the greatest possible benefit.

Your committee are unwilling to conclude their labors without very decidedly urging the adoption of a system of making returns which shall tend to relieve the medical examiner from the deserved charges of errors of omission and inaccuracy of statement.

Each examiner should be provided with printed directions of procedure in all cases likely to require his services. The method of making a *post-mortem* examination should be so ordered as to demand a systematic, clear and objective statement of the physical condition of the various organs of the body and the appearance of its surface. The inquiry should be strictly limited to the cause and manner of death, and printed blanks might be prepared for general use. These should comprehend not only all the data necessary to prove the assumed cause of death, but also the evidence which might be needed to control the assumption of other theoretical possibilities of death.

In cases of suspected homicide another medical examiner might be called as the medical witness allowed by law. Certain of the district attorneys authorize a medical expert to be employed at the outset in these cases at the discretion of the medical examiner, and such practice would undoubtedly become general if requested. If the suspicion of homicidal violence is urgent the police or constabulary as well as the district attorney and justice should be immediately notified, that the surroundings of the dead person may be investigated by the authorized agents of the law with as little delay and as little alteration as possible.

The statute now provides that duplicate copies of the records of an autopsy shall be deposited with the district attorney and a justice. If one of these copies were periodically filed with some duly appointed board or official of the State, the appointing power would be provided with easily available evidence concerning the qualifications of incumbents.

The valuable suggestion from the reader of the paper that a central commission be appointed to sift the returns from the medical examiners, for the sake of furnishing the legal officials with the results of this analysis, might be embodied in the necessary recommendation. In his inaugural address previously referred to, the governor advised that the medical examiners be required to report the cases investigated by them to the State Board of Health, Lunacy and Charity. If a State Board of Health is established by the present Legislature it is possible that the responsibilities of the desired commission might be advantageously placed in its hands.

In conclusion your committee recommend that a committee be appointed to bring before the next Legislature the desirability of such action as shall refer to an appropriate State Board or official, the establishment of definite and detailed rules of procedure for medical examiners, and the collection and preservation of their records.

GEORGE B. SHATTUCK, M.D.

BOSTON, Feb. 22, 1886.

CAMBRIDGE SOCIETY FOR MEDICAL IMPROVEMENT.

COMPLIMENTARY DINNER TO DR. MORRILL WYMAN, FEBRUARY 17, 1886.

A COMPLIMENTARY dinner to Dr. Morrill Wyman was given February 17th, at the Parker House, by the Cambridge Medical Improvement Society. Between thirty and forty physicians of Cambridge and vicinity, members of the Society, were present. The present year is the forty-ninth of Dr. Wyman's practice. After this long service he has thought best to retire from the duties of family physician, continuing simply those of consultant.

After the dinner which occupied the time from 6.30 to 8.30, Dr. S. W. Driver, the president of the Society, opened the speaking, referring to the pleasent relations which had always existed between Dr. Wyman and himself, to Dr. Wyman's progressiveness, to his wise conservatism, and to the healthful conception of what is to be expected from medical treatment with which he had imbued his patients. Dr. Driver also spoke of his valuable services as a member of the Board of Overseers of Harvard University.

DR. WYMAN then acknowledged the honor paid him by the Society in desiring to meet him socially. He thought that the physicians of Cambridge are remarkable for their urbanity and good will to one another. Among the various influences which maintain a high standard in the medical profession of this City, Harvard College in its varied relations to the people of Cambridge, is not the least. Dr. Wyman then spoke of the Cambridge Hospital, and expressed the hope that the physicians would willingly assume the duties incident to the complete success of such an institution. In closing, he proposed the following sentiment: "The physician, consecrated to humanity; may he ever be true to his sacred office!"

DR. W. W. WELLINGTON, who began practice one year later than Dr. Wyman, recalled early reminiscences of medical education and practice.

DR. J. T. G. NICHOLS responded to "The Cambridge Medical School." He read one of the early circulars which declared the purposes of the school, and outlined the course of study. The school was organized as a department of the Lawrence Scientific School. Its list of instructors contained the following names: Jeffreys Wyman, Morrill Wyman, Louis Agassiz, Asa Gray, Joseph Lovering, and Josiah P. Cooke, Jr., Morrill Wyman holding the position of adjunct professor of Theory and Practice. In commenting on the various instructors, Dr. Nichols spoke in warm praise of the faithfulness, kindness, and lofty character of Jeffreys Wyman.

"Courtesy of the senior and loyalty of the junior" called up Dr. J. L. Hildreth, who spoke of the kind reception which Dr. Wyman gave him when he came to Cambridge, and of the conviction of Dr. Wyman's sincerity and professional honor which he received at his first interview.

DR. L. R. STONE, of Newton, gave a brief history of paracentesis thoracis, referred to the first case in which Dr. Wyman performed it, and spoke in high terms of his valuable service in demonstrating the benefits of the operation, and in bringing it into general practice.

DR. A. P. CLARKE proved himself the poet of the evening, and entertained the company by sounding the guest's praises in verse.

"A sore back never helped a poor brain" brought Dr. E. R. Cogswell to his feet, who said that although a number of years have now passed since Dr. Wyman was a member of the School Board, the effect of his wise counsel is still evident in the improved methods of school discipline, corporal punishment having been practically abolished, and the present methods of school government inaugurated through Dr. Wyman's efforts.

DR. R. L. HODGDON, of Arlington, in speaking of "the physician in consultation," said that he had called Dr. Wyman in consultation oftener than he had any other one physician, oftener, perhaps, than all others; that he had received from him valuable assistance; that he had found him a man who would not assert more than he had good reasons for asserting, and who, in puzzling cases which admitted of no solution was not afraid to say, "I don't know."

Surgeon-General A. F. HOLT represented the State, and expressed his high regard for Dr. Wyman's public spirit in all the relations of true citizenship.

DR. J. B. TAYLOR responded to "The Cambridge Hospital." He briefly sketched the history of the movement for its establishment, referred to the care exercised in planning and constructing the building, and ascribed the success of the enterprise as far as it has been carried, the thoroughness of construction, and the excellent adaptation of the building to its requirements, to Dr. Wyman's careful investigation and foresight, and to his watchful oversight of the work of contractors and employés.

DR. H. P. WALCOTT's subject was Dr. Wyman's literary work. He spoke in particular of his Thesis on Ventilation, afterwards enlarged and published in book form; of his essay on Autumnal Catarrh, and of his essay read before the Massachusetts Medical Society in 1863, on the Reality and Certainty of Medicine.

The various speakers enlivened their remarks by personal reminiscences, and paid high tributes to Dr. Wyman's character and ability.

DR. J. W. BEMIS sent a letter expressing regret at his enforced absence, and his high appreciation of Dr. Wyman's attainments, and of his services to the profession.

Soon after ten o'clock the company sang "Auld Lang Syne," and dispersed.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED meeting February 15, 1886.

DR. FREDERIC S. DENNIS read a paper on

LAPAROTOMY IN THE TREATMENT OF PENETRATING AND VISCERAL INJURIES OF THE ABDOMEN.

Having referred to the importance of the subject, he said that this was an operation which, limited to penetrating wounds of the abdomen, no surgeon had ever performed until within a few months past. It was therefore natural that great interest should be felt in it; and there was still much diversity of opinion in regard to it. The present was, then, a fitting time to discuss the propriety of the procedure. He felt obliged, he said, to differ from the late Dr. James R. Wood in regard to this; and, in the light of the recent advances in antiseptic surgery, he did not doubt that that distinguished authority would have modified his views upon the subject. The methods which now render laparotomy possible in such a large proportion of cases were inadequately understood a few years ago. Experimental research has now rendered it possible to perform operations which were formerly impossible, and without the pale of legitimate surgery. The crucial test of experiment had demonstrated that, under proper conditions, the opening of the peritoneal cavity was not attended with any great danger.

Having remarked that shock was not to be considered by the surgeon in performing laparotomy, he went on to speak, first, of

PENETRATING STAB-WOUNDS.

He related in full the case of a young man of twenty-two, who was admitted to his wards at St. Vincent's Hospital in November, 1885, suffering from two abdominal wounds inflicted with a knife. The intestines which were perforated protruded, and there was fæcal exudation, but not into the peritoneal cavity. The wounded intestine was sewed up with catgut sutures, and, after a thorough examination had been made for other wounds in it, returned to the cavity, and the external wound closed. The patient made a perfect recovery, and was presented to the members of the association for inspection of the cicatrix. Dr. Dennis remarked in connection with the case, that the operation of exploratory laparotomy was not called for in this instance, because the intestines protruded, and could be drawn out and sufficiently examined without such an operation, and that a concealed wound would have been much more dangerous.

A second case recently under his care was that of a negro, fifty-seven years of age, who was admitted to St. Vincent's Hospital December 20, 1885. He had been stabbed in the umbilical region, to the left of the median line; and from the wound, which was one and a half inches in length, protruded a finger-shaped piece of omentum, the latter being tightly constricted by the wound. Antiseptic gauze was immediately placed over the parts; and three hours after the accident, laparotomy was performed under the strictest antiseptic precautions. A vertical incision was first made in the median line, and then a second one diagonally, joining the wound to this. The viscera were thoroughly examined, from the stomach to the sigmoid flexure of the colon. The small intestines were turned completely out of the body, and the omentum and mesentery carefully inspected; but no injuries were found. This patient also had made a complete recovery, and, like the other, was presented. The piece of omentum which had protruded from the wound was also shown. Dr. Dennis said that it might be objected that laparotomy was not necessary in this case, but he would remark that this fact was not known at the time. If the intestines *had* been wounded, and laparotomy had not been performed, the patient would undoubtedly have died. The laparotomy was necessary, therefore, in order to find out what the actual condition of affairs was. This, he believed, was the first exploratory laparotomy which had ever been made in the case of a stab-wound, where it was not known that the intestines were wounded. Stab-wounds however, were not so dangerous as gun-shot wounds.

In another case of this kind, he would recommend that the wound itself should be enlarged sufficiently to make an examination of the intestines before performing laparotomy proper, this procedure being a little more conservative. The operation in this instance had not been sudden and unpremeditated, but was the result of much study and experience in connection with other similar cases. He then related four cases in which death had resulted under the old methods of treatment. In the fourth of these, a volvulus was found at the autopsy, and he had no doubt that laparotomy would have saved the life of the patient, although there was no wound of the intestine. He was of the opinion

that this condition was the cause of many deaths, and said that it offered a new indication for laparotomy.

DR. DENNIS then gave reports of a number of other cases, accompanying many of them with "the presentation of specimens." The first of this series was also an instance of volvulus, resulting from the spasmodic condition of the intestines. In this case, although laparotomy was performed, the patient died, not from the operation, but from fæcal exudation. A resection of the injured intestine was made in this case. In the second, death also occurred from fæcal exudation. There were seven perforations of the intestines, but the sutures with which the injuries were repaired held so firmly that no leakage occurred when a strong stream of water was turned into the gut. There were three cases in which the patients recovered after laparotomy, the stomach being perforated in one of these. Dr. Dennis gave a list of the various cases of laparotomy in stab-wounds reported by various surgeons. Of six cases of his own, four recovered and two died.

He next went on to speak of laparotomy in pistol-shot wounds of the abdomen, and, in the first place, referred to Dr. W. T. Bull's remarkable case, which, he said, was a new application of laparotomy. He then mentioned two cases of his own.

The first was that of a young man twenty-three years of age, who was admitted to the 99th Street Reception Hospital January 2d, 1886, suffering from a penetrating wound of the abdomen, caused by a 32-calibre ball. Severe shock was present, but laparotomy was performed, when he found that there was the most profuse hæmorrhage in the cavity. The examination showed that the principal source of this was the veins in the transverse fissure of the liver. There was no wound of the intestines. On account of the extreme exhaustion of the patient, transfusion was resorted to, twelve ounces of a saline solution being injected into the radial artery. This was followed by marked benefit, and the same thing was, therefore, repeated every four hours, the canula in the meanwhile being retained in the artery. At the end of forty-eight hours, however, the patient died, and at the autopsy, the bullet was found imbedded in the right lobe of the liver, the wound being necessarily a mortal one on account of the irreparable injury to large blood-vessels. (Specimen exhibited.)

Another patient, aged twenty-two, was admitted to the same hospital January 10th, 1886, also suffering from a penetrating abdominal wound inflicted by a 32-calibre pistol. He had marked shock, and laparotomy was resorted to by Dr. Dennis. There was fæcal exudation, and seven openings in the intestine, with one in the mesentery, were found. The hæmorrhage was so enormous that, on account of the alarming condition of the patient, the operation had to be abandoned before its completion, and death ensued in forty-eight hours after the injury. At the autopsy the cavity of the abdomen was found completely filled with blood, but the sutures which had been made in the intestines rendered them perfectly water-tight.

Dr. Dennis remarked in connection with the frightful and uncontrollable hæmorrhage met with in these two cases, that at present the great desideratum in laparotomy for penetrating wounds was some means of arresting hæmorrhage from such large vessels as the vena cava, the iliac veins, and the portal veins, and it had occurred to him that this might possibly be accomplished by constriction of the thighs and the waist for a sufficient time to enable the surgeon to secure the bleeding trunks. When this point was accomplished, he believed that laparotomy as an operation would meet with the most brilliant success.

He then referred to some cases in which laparotomy was not performed. In one instance, ten perforations of the intestines were found at the autopsy, and the failure to perform the operation therefore deprived the patient of the only chance of recovery that he had. In this case, the existence of perforations was not suspected by the surgeon in charge until shortly before death, so that it forcibly illustrated the advisability of exploratory laparotomy even in comparatively favorable cases. Where there was perforation of the intestines, the injury was necessarily fatal unless laparotomy was resorted to. He thought it highly desirable that surgeons should report all their cases of laparotomy, whether successful or not.

The third indication mentioned was rupture of the intestine. A number of cases, illustrated with specimens, were related. In two the patients were run over, and in the others, injuries of various sorts were received. Dr. Dennis said that so far as he had been able to find, only two cases had been reported of laparotomy for rupture of the intestine due to traumatism. One of these had been reported by Mr. Owens, of London, in the *Lancet*. The patient was struck in the abdomen by a heavy plank, and an exploratory laparotomy was performed, but a fatal result ensued. He then referred to cases reported by various surgeons, which showed the necessity of laparotomy, although it was not performed.

In speaking of this class of cases he referred to emphysema of the tissues and loss of hepatic flatness on percussion as indication of perforation, and to several other points. Collapse was the only constant symptom, but it was not pathognomonic. In cases of rupture, the rupture was always in the small intestine. The contraction of the muscular fibres usually prevented fæcal extravasation. The performance of laparotomy in these cases enlarged the domain of abdominal surgery, although as yet no successful result had been reported.

He then referred in detail to the various signs of visceral perforation in general, among which are mentioned: (1) Fæcal extravasation. This was a positive one. (2) Emphysema of the tissues. This was also a positive one, and was of very great importance. (3) Shock. The persistency of the shock was of more significance than its severity, and when it was persistent, it afforded a strong link in the chain of evidence. The shock, he went on to say, was more apparent than real, being due rather to the sympathetic than to the cerebro-spinal system, as was also the case in strangulated hernia. He thought its presence should not deter the surgeon from performing laparotomy, and in his own cases, he had found that the collapse improved after the opening of the abdomen. Shock, however, offered no direct evidence of perforation, and a number of cases are on record in which, although there actually was perforation, there was little or no shock present, and death occurred almost without warning. (4) Tympanic resonance over the liver. This was an important sign, and Professor Flint had found that wherever there was persistent flatness over the liver, no perforation was present.

Having briefly mentioned sudden meteorism, subnormal temperature, fixed localized pain, vomiting and

bloody stools, and other signs which were sometimes met with, he stated that, in consequence of the length of the paper, he would be obliged to omit the part of it devoted to the technique of the operation, and would proceed to give the conclusions at which he had arrived, which were as follows:

First. That penetrating stab-wounds of the abdomen are less fatal than penetrating gun-shot wounds, but that the former are fatal in too great numbers to justify reliance on the older methods of treatment.

Second. That if the stab-wound has injured the intestine or any abdominal organ, laparotomy is indicated. That it may be indicated also in cases where the gut is not perforated, but where the gut may become twisted, as a result of the stab-wound.

Third. That in a penetrating stab-wound in which doubt exists, the diagnosis should be made certain at once, in order to pursue a proper line of treatment.

Fourth. That laparotomy offers no additional danger to the patient, if properly performed with the strictest antiseptic precautions.

Fifth. That while the number of cases in which there was an exploratory laparotomy made in stab-wounds of the abdomen affords insufficient data upon which to establish any fixed rule of practice, the same principle which is recognized in the performance of laparotomy for gun-shot wounds of the abdomen, is one applicable to penetrating stab-wounds.

Sixth. That the enlargement of the original wound for an examination of the peritoneal cavity will not enable the surgeon to exclude, in all cases, fæcal extravasation, perforation, volvulus, and hæmorrhage. These may all exist, and yet no evidences of their presence be manifested upon inspection through a small opening.

Seventh. Neither the size, shape, character, and velocity of the bullet, the attitude of the patient at the time, nor the kind of weapon used to produce a stab-wound, seem to him to influence the question of laparotomy.

Eighth. It is possible to have a fatal hæmorrhage from the large venous trunks in the abdomen, and this hæmorrhage not be discovered until the cavity is about to be closed.

Ninth. That the sutures, if properly applied, will close the perforation in every case, no matter how lacerated the wounds are, or the sutures will close the wound in case of resection of the gut, so that no leakage will occur if water is forced through the sutured intestines.

Tenth. The success of laparotomy is to be attained when every arrangement is complete and perfect.

DISCUSSION.

DR. JOSEPH D. BRYANT said that it was unnecessary for him to state that he was heartily in favor of laparotomy, but the two distinct forms of the operation should always be considered separately, namely: exploratory laparotomy, and laparotomy in its entirety. The exploratory operation he said he would employ far more frequently than is at present the case, believing, as he did, that when performed under proper conditions, it exposed the patient to no unusual danger. It was a perfectly simple matter to open the abdomen; but when called upon to make a thorough examination of all the viscera, to arrest hæmorrhage at all bleeding points, to suture the intestines, and to perform the toilet of the peritoneum, it was a very different matter, and a procedure which was likely to employ from one to three hours. He said he called attention to this point in order that the gravity of the operation of laparotomy in its entirety might be fully understood.

Whether shock was present or not, it was perfectly justifiable to perform exploratory laparotomy, and the incision might be in the median line or in the seat of the wound, according to circumstances. In regard to shock, he said it was a principle pretty well established, that penetrating gun-shot wounds of the abdomen, provided they do not cause hæmorrhage or the injury of nerve-trunks, are not followed by much shock. When there was severe shock and subnormal temperature, it generally indicated hæmorrhage, and, therefore, as Dr. Dennis had remarked, severe shock was no contra-indication for laparotomy. He would not consider a case of laparotomy in its entirety, one in which there were found no injuries of the intestines or other viscera. If this was the case, it was merely an exploratory laparotomy. Hæmorrhage was a very important symptom, and it was absolutely necessary that any bleeding point should be satisfactorily secured. Not infrequently, very slight oozing became changed to profuse hæmorrhage when the abdominal contents were returned to their places, and the cavity was closed up. Experiments which he had made on dogs (shooting them in the abdomen, and then performing laparotomy), had further convinced him of the extreme importance of hæmorrhage in gun-shot wounds of the abdominal cavity.

DR. E. G. JANEWAY said that the absence of hepatic dulness was a good general guide as to the existence of perforation, but there were a certain number of instances which simulated this condition. Thus, in a case of typhoid fever under his observation, in which on account of the loss of liver dulness, perforation was supposed to have taken place, it was found at the autopsy, that the resonance over the hepatic region was, in reality, due to the tilting of the liver. In regard to the operation, one possibility had occurred to him. Eberth, in his experiments on dogs, had found that by immersing the abdomen in a serum bath 98°, thrombosis and peritonitis could be prevented. Possibly, therefore, it might be advisable to operate on human subjects in the same way. It would hardly be safe to use bichloride of mercury as the antiseptic under the circumstances, but a warm saline solution might be employed for the bath.

DR. J. W. S. GOULEY said that he believed that the views expressed this evening were sound. The operation of laparotomy was justifiable when we had reason to believe that the hollow viscera had been injured. He then related two cases which had come under his own observation. The first was that of a young soldier twenty-two years ago, who suffered from a bayonet wound which passed completely through his body. It was not clear what organs had been injured in its course; but nothing was done, and the patient got well without a bad symptom.

The second case was one in which there was a pistol shot wound which also passed completely through the body. It injured the right lobe of the liver and the lower lobe of the right lung; and bile flowed freely out at both openings, mingled with the pus. In this case also recovery took place under the expectant plan of treatment. During the war he had in fact seen several cases which resulted successfully in a similar manner. At the same time, if he were to meet with

such cases to-day, he did not hesitate to say that he should prepare himself to open the abdomen.

DR. H. M. BIGGS said that in regard to the loss of liver dulness, he had met with a case which showed that this could not be relied upon as an infallible sign of perforation. The patient was suffering from peritonitis, and when the absence of hepatic dulness was detected, it was supposed that perforation had occurred. There was no operation, and the patient died; when it was found at the autopsy that the cause of the resonance in the hepatic region was that the intestines had become forced between the liver and the abdominal walls, and that no perforation had taken place.

The President, DR. C. A. LEALE, then related an interesting case of penetrating wound of the abdomen, with recovery, which had been under his care during the late war.

Recent Literature.

Facts and Mysteries of Spiritism Learned by a Seven Years' Experience and Investigation. By JOSEPH HARTMAN. Philadelphia: T. W. Hartley & Co. pp. 380.

If seven years of ardent investigation does not qualify a man to tell much about the wonders of "spiritism," it would seem as though he were spending his time to little purpose.

This book seems to be the candid and honest statement of one who is thoroughly convinced of the fundamental assumption of modern spiritists. Mr. Hartman claims personally to have had evidence which places beyond doubt the reality of all that Swedenborg experienced or Swedenborg's modern successors claim; spirits have conversed with him and made him their instrument, looking through his eyes, as one looks through a window (page 234), hearing with his ears, and making use of the perceptions in his mind to acquaint themselves with what was going on in the world (see Sequel); he for a while surrendered himself willingly to their influence till he found himself mocked and betrayed by his celestial visitants. In fact, the author eventually discovered to his horror that the "spirits" are all vain, lying spirits, deceiving and leading astray "demons," "whose mission is to destroy men's souls," and though they often personate the great and good, yet "they are always and without exception evil."

The book is evidently written with a good intent, and it is very probable that there is in this land a large class of readers to whom such an "exposure" may be beneficial and salutary, calling them back from unprofitable ultra-mundane speculations and frivolities to the practical realities and duties before them.

To medical readers this work will have an interest of a different kind. How, in accordance with known laws of the nervous system, to explain the curious psychological problems which are presented in every page of Mr. Hartman's volume; this is a subject which cerebral physiologists and especially alienists would do well to grapple.

E. P. H.

—M. Paul Bert, the eminent French physiologist, has accepted the political appointment of governor of Tonquin.

Medical and Surgical Journal.

THURSDAY, MARCH 4, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

DIABETES AND PERFORATING ULCER OF THE FOOT.

ANY person who has met with even a few cases of perforating ulcer of the foot must have found difficulty in classifying them as to their origin and therefore in placing their treatment on an appropriate basis. Certain ulcers of the plantar surface are evidently coincident with, and apparently the result of nervous lesions; others are as evidently not at all connected with nervous lesions. In an interesting article in the *Revue de Chirurgie*, Dr. M. Jeannel, Professor of Clinical Surgery in the School of Medicine of Toulouse, makes certain suggestions in connection with the *mal perforant*. In the first place he makes two distinct classes of the disease, a distinction not unrecognized by others; the false, which consists of inflammation and suppuration of the callosities or of the subjacent bursæ of the foot, and which are purely of local and traumatic origin: the true, the seat of which is variable and in no necessary relation with the callosities and bursæ of the plantar surface; whose gravity is great as compared with the benignity of the first form; which recur with discouraging perseverance and are often accompanied by anæsthesia more or less extended and which are in a word veritable trophic troubles. It is in these last that degenerative lesions of the nerves have been demonstrated, while in the first nothing of the sort can be found.

Arnozan[1] showed the frequency of perforating ulcers in toes previously frozen and where in consequence a primitive neuritis exists; following traumatic sections of the sciatic nerve; wounds or simple contusions of the spine; accompanying locomotor ataxia and more rarely with progressive muscular atrophy; and he concluded that the perforating ulcer of the foot had in a great number of cases a nervous origin either central or peripheric. (Nicaise claims that while "the occurrence of a perforating ulcer is singularly favored by the previous existence of trophic disturbances of nervous origin, this affection is not met with unless a local compression intervenes.")

[1] Des Lésions trophiques consécutives aux maladies du système nerveux. Paris, 1880.

In the same way are explained the phenomena which sometimes precede the plantar ulceration, such as the shooting pains, the motor troubles, the lesions of the nails, and the erythemas, as well as the frequent recurrence of the disease which presents itself either in the cicatrix, at some other part of the foot or upon the stump, if amputation has been practised. It is also true that a number of cases of *mal perforant* occur with shooting pains, motor and sensitive troubles, lesions of the nails and erythemas, without antecedent frost bites or section of the sciatic, without wound or disease of the spine of any sort. Something further remains then to be done in fixing upon the cause of these apparently spontaneous cases.

Dr. Jeannel has had an opportunity of treating two cases of perforating ulcer in individuals in whom none of the above named nervous troubles were present but who were the subjects of well-marked saccharine diabetes. He has also watched a third case in the practice of one of his colleagues in which were five ulcers on the left foot with a spontaneous amputation of the toes; in which case there was no spontaneous or traumatic lesion of the medulla, but sugar was present in the urine. Dr. Jeannel naturally inquires if the relationship of cause and effect is possible between diabetes and perforating ulcer.

As to the possibility of such a relation of cause and effect he thinks it incontestable, admitting on the one hand that true *mal perforant* is a trophic trouble recognizing as cause a series of known or unknown central (or peripheric) nervous affections, which seems to be absolutely demonstrated; and admitting on the other hand that diabetes is itself a nervous affection. The last factor of the problem is to-day only a strong presumption, since the encephalic anatomo-pathologic lesion is only rarely demonstrable, but one must take account of the fact that in physiological experiments it is possible by the lesion of a determined point of the nervous centre to produce glycosuria, and on the other hand nervous accidents occur in diabetes. As a central nervous lesion diabetes may engender trophic lesions and it does give rise to many. What in effect are carbuncles, furunculous and ecthymatous outbreaks, gangrene, diabetic ulcers, cataract and the spontaneous amputation of the toes already referred to, if not veritable trophic troubles. These same lesions are so characterized when they are observed in connection with known medullary lesions: why refuse them the same quality when they are observed in connection with diabetes.

En résumé, Dr. Jeannel thus states his case: On the one side *mal perforans* is a trophic trouble observed in many central nervous affections sometimes alone, more often accompanied by other lesions of the same group: on the other side it is very probable that diabetes is a central nervous affection, it is certainly a general dystrophy; and lastly, one observes in diabetics cases of *mal perforans* alone or accompanied by well characterized trophic lesions. Observation must finally settle the relationship and resolve at least in part the double question, the etiology of *mal perforans* and the nature of diabetes.

Dr. Jeannel quotes four cases beside his own, and mentions some references to the same possible connection by other writers. It is evident that the connection is by no means established; if it exists and is at all common it must often have been overlooked; but the article in question will stimulate others to watch more carefully for the possible constitutional condition behind the local lesion of *mal perforant*.

ANNUAL REPORTS OF THE PRESIDENT AND TREASURER OF HARVARD COLLEGE.

The reports of the President and Treasurer of Harvard College for the year 1884–85 contain the usual information in regard to the condition of the various schools and departments of the University and the changes which have taken place in the twelve months.

The report of the Dean of the Medical School is of more particular interest for our readers. The year in this school was one without especial changes, marked rather by the appreciation and utilization on the part of both teachers and students of the ample accommodations afforded by the new building. Some modifications in lighting, heating and ventilation were found necessary and have been made. Some valuable additions have been made to the Warren Museum by the Anatomical Department, and in each of the laboratories for physiology, for chemistry, hygiene, pathology, histology and embryology, some original work has been carried on, and much of it has found publication.

The whole number of students in attendance during the year was 257; during the first term 254; during the second term 235. Of these 133 had literary or scientific degrees; 47+ per cent. of the whole number in attendance having the degree of A.B., whilst 76+ per cent. of the students at the Law School and 80+ per cent. of those at the Divinity School had this degree. There were 67 applicants for the degree of doctor of medicine in the three years' course, of whom eleven were rejected; there were six applicants for the degree in the four years' course, of whom three were rejected, and of the three who received this degree two received it *cum laude* and with it the degree of A.M.; of the 16 students, however, composing the fourth class ten postponed graduation.

The important question before the school at present is that of prolonging the course required for the degree to four years. The present voluntary fourth year was established in 1878 as a compromise between the old three years' course and a compulsory four years' course. It was regarded as tentative and experimental. During the eight years since the course was established the following have been the number of students taking it in each successive year: one, two, nine, nine, ten, twelve, sixteen, eighteen. These fig-

ures would certainly seem to indicate an increasing demand for the course, but, when informed by the Dean that in 1884–85 ten of sixteen postponed graduation and three of six who applied for the degree were rejected, we cannot be sure how far the increase in number may not be due to the survival of the *un*fittest, or how far membership in the fourth-year class may not be evidence of torpidity rather than of zeal. In Germany the recurrent student, after a certain time, acquires the title of "moss-head."

The school will have to decide a double question — whether a four years' course is in the abstract desirable, and whether it can afford to furnish such a course. There can be no doubt that a higher standard of medical education would enure to the welfare of the profession and of the public; we query however, how far the average American student will profit by a further development of laboratory, at the expense of clinical teaching. The present tendency is to supplement the work of the degree-giving schools by courses in the Post-Graduate Organizations and in the Polyclinics, and this is a tendency which, with the practical instincts of the country as well as the specialization of branches of medicine and surgery, is likely to increase rather than diminish. We believe we may venture on the statement that the usefulness of the present voluntary fourth year has not proved itself to be proportioned to the inconveniences which it entails.

In regard to the feasibility of a compulsory four years' course, the Dean, apparently guided by the figures, considers that the course having steadily gained in popularity since it was first established, it is not too much to hope if it were made compulsory, that the additional fees thus obtained would more than compensate for the loss of those students who would seek elsewhere a diploma which could be more easily gained. On the other hand, the President of the University seems more inclined to doubt the present feasibility of taking such a step. In his comments on the Professional Schools he says:

"The Medical Faculty has given abundant proof that it wishes to do the best work, rather than to attract a large number of students; but it feels obliged to measure carefully the risks to which the prolongation of the course might expose the present excellent School. During the past four years nine per cent. of the graduates of the School have taken the four-years' degree. To maintain the present salaries and establishment the School has, and must have, an income of $64,000. At present about $53,000, or more than four-fifths of the School's income, are derived from student's fees, and the tuition fee is higher than in any other department of the University. How great the reduction in the number of students would be, if four years' study were required for the degree, no one can tell; but a reduction of twenty per cent. seems a low estimate. Such a reduction from the school of the current year (1885–86) would give 211 students in attendance instead of 264. To provide against even this moderate reduction in the amount of student's fees an additional endowment of $210,000 would be needed."

Last year the school had a surplus of $2039.10, according to the treasurer's report. There has been a considerable increase in the expenditure for salaries, and a large reduction in other expenses incident to the occupancy of a new building. For the information of possible benefactors of the Harvard Medical School we may repeat a suggestion that a sum of $10,000 could be acceptably bestowed as a scholarship; a sum of $100,000 as the endowment of a professorship, and a sum of $500,000 for the establishment of a hospital connected with the school.

The Dental School is still struggling against many difficulties, and is still greatly hampered for want of funds. In spite of this it has bravely established an entrance examination, which, though of the simplest character, has had the effect of reducing the first class (1885–86) to a third of the average number in previous years. The debt of the School has been reduced, its equipment improved, and its instruction rendered more complete; but these results have only been attained at the expense of continued sacrifices on the part of the teachers.

The Veterinary School has largely increased both its receipts and expenditures. There is a small deficit in its current account which added to the cost of enlarging its hospital (over $7,000) makes its present debt about $7,500. The school urgently needs an endowment of $50,000. The Secretary reports that:

"As a teaching institution it may now perhaps be said, that with the addition of two or three veterinarians to its staff which it is hoped that its own graduates will supply the coming year, the School is at once ready to take and hold a leading place among institutions of the sort. But before it can be expected to fill the entire field of its usefulness — in the way of biological research, and in the discovery of means to prevent the extension of communicable and preventable diseases among animals, and from animals to mankind — some of its officers must be freed from the necessity of maintaining themselves by private practice."

THE MEDICAL EXAMINER SYSTEM.

WE beg to call our readers' attention to the report published on another page of this issue, of the Committee appointed by the Boston Society for Medical Improvement, to consider the operation of the medical examiner system in Massachusetts. In an editorial (December 17, 1885), commenting on the circumstances which gave rise to the appointment of this Committee, we reserved any extended discussion of the subject until the appearance of its report. The report speaks for itself, and should be read by those interested in the extension of the system to other States.

MEDICAL NOTES.

— Dr. Daniel G. Brinton, of Philadelphia, has been announced as laureate of the Société Américaine de France for 1885, and has been awarded the medal of the Society for his works on the aboriginal tongues of America.

— It appearing that Oliver Dean Root, M.D., 1854, died at New Orleans in 1863, in the discharge of his duties as an assistant-surgeon of the United States, it has been recently voted by the corporation of Harvard University, that his name be placed on the tablets in Memorial Hall.

— *L' Union Medicale*, January 9, 1886, contains the following recipe of Professor Bouchut for painful dentition in infancy.

R.—Cocaine Muriate	1 part.
Sodium borate	1 part.
Syrup of marshmallows	20 parts.
Syrup of poppies	10 parts.—M

S. Gently rub the gums with the syrup four times daily.

— A correspondent of *Science* writing from St. Petersburg says that a movement is under way for establishing a female medical school in that city. A few years ago, ladies received instruction at one of the military hospitals, and some of the graduates are practising with honor. Later this instruction ceased, as the minister of war would not continue the subsidy given before, nor allow the use of the buildings. Now the matter is under discussion in the duma (city assembly) of St. Petersburg. There are also private subscriptions for this end, and lately the great importance of female physicians is especially insisted upon for central Asia and eastern Transcaucasia, that is, provinces where the great mass of the people are Mohammedans.

— A correspondent of the *Therapeutic Gazette*, writing from Berlin, says: "In the children's department at the University Hospital of Berlin, there is a collection of some three hundred nursing-bottles of various sizes and shapes, all provided with a long rubber tube, which encloses a piece of litmus-paper colored red. No commentary is needed. It is quite clear that the presence of lactic acid in the tube suffices to explain many obscure disorders of the alimentary tract for which the physicians are often at a loss to find a satisfactory explanation. The writer has repeatedly witnessed that mothers returned to the Polyclinic and testified to the rapid recovery of their children after withdrawal of the patent nursing-bottles. In one instance, the tube was found to be made of lead, and to have given rise to serious constitutional symptoms in addition to the gastric irritation. In view of these facts, the attending physicians of the Polyclinic make it an invariable rule to inquire as to the nature of the nursing-bottle in every child presented for treatment on account of digestive disorders.

BOSTON.

— Some ten days ago a schooner-load of Maine lobsters were inspected at a Boston wharf. As they were barely within the required length — ten and a half inches — they were allowed to be disposed of. As three other schooners were on the way to, or about sailing for this city at the time, similarly loaded, and as neither of them arrived, the Deputy Fish Commissioner had reason to believe that their skippers had got telegraphic notice of the rigid measures taken here to prevent the disposal of short lobsters. His surmises proved correct, for last week a despatch from Portland announced several seizures — one of more than three thousand of the immature shell-fish — the dealers paying hundreds of dollars in fines. The commissioners of Maine and Massachusetts are working together in the matter. It is said that one year's growth beyond the law's limit nearly doubles the size of the lobster. The penalty in Maine is the fine of $1 for each specimen seized; in Massachusetts it is $5.

— At the request of the President of Harvard University, Prof. R. T. Edes delivered an address last Tuesday evening before the Cambridge students on the subject of medicine as a profession. Rev. Philip Brooks and Judge Oliver Wendell Holmes, Jr., had previously spoken about the ministry and the law.

NEW YORK.

— The commencement exercises of the Buffalo Medical College were held February 23, when diplomas were conferred upon a class of forty-three. The address to the graduates was made by the President of Cornell University, Mr. C. K. Adams.

— At a meeting of the Medico-Legal Society held February 18, the Hon. Erastus Brooks, of the State Board of Health, read a paper on "What the State Owes to the People, and What the People Owe to the State," in the course of which he said that the health of the people was the first duty of the State, and, although commerce and quarantine were perpetual enemies, that the State should protect the people from such diseases as cholera, at whatever cost to commerce. The expenditure of money for sanitary purposes was undoubtedly an actual pecuniary benefit to the country, as each life saved by precautionary measures was computed to be worth a certain sum of money, in Great Britain, each life being computed to be worth $795. The people, on the other hand, owed sympathy and co-operation to the State in return for protection. Health at home means health everywhere.

— A coroner's inquest was held February 26th, in the case of Thomas E. Roche, who died in the German Hospital on the 17th ult., from the effects of chloroform administered for anæsthetic purposes during a surgical operation. A number of physicians were present as spectators, and considerable medical testimony was taken in regard to the action of chloroform on the human system under different circumstances, and in varying conditions of health. The question at issue was, whether the hospital surgeons had acted properly in administering chloroform to the patient when death had been caused by it. The jury, which consisted of physicians, brought in a verdict declaring that Roche came to his death by paralysis of the heart while under the influence of chloroform, the patient being in a depressed state of health from malignant disease of the cervical glands. Their report further said: "Inasmuch as the chloroform was of good quality, and administered by a competent physician, in a competent manner, and with the consent of the patient, no blame can be attached to the hospital authorities or the physicians in charge."

— At a meeting of the New York County Medical Society, held February 22d, Dr. John C. Peters read a paper on "The Present and Future Water-Supply of the City," in the course of which he gave a description of the proposed Quaker Bridge dam. The Committee

on Hygiene, of which Dr. Peters is Chairman, are unanimously in favor of this great work, because of the immensely increased supply which it will afford. The following are the conclusions at which the Committee have arrived: "That the Quaker Bridge dam is unobjectionable from a hygienic point of view; that the Sodom dam should be constructed at once, in order to furnish a quick water-supply; that means should be taken to improve the quality of the water, including the construction of a system of sewers to receive the sewage of the Croton water-shed; and that a safety strip of land, a quarter of a mile wide, to preserve the purity of the Croton River, should be purchased." Dr. Peters said that there was no doubt that the Croton supply at its source, is the purest furnished to any city, and he thought that by proper protection against sewerage, the water-supply of New York might be endorsed the best in the world.

— The third annual report of the New York Skin and Cancer Hospital shows that marked and satisfactory progress has been made in the development of the institution during the past year. Besides the City Hospital in East 34th Street, where, since its establishment three years ago, more than three thousand cases have been treated in the different departments, a country branch of cottage pavilions is now conducted at Fordham Heights, near High Bridge, and within the city limits. The latter property contains about sixteen acres of land on high ground, commanding a view both of the Hudson River and Long Island Sound, and is to be made the leading pattern of the hospital system. There are at present two cottages, the first of a series which, as the work develops, it is to erect on the property. The pavilions may be built by individual donors and named by them, and they will all be administered from a central building, which is already prepared for the purpose. About 140 of the 1,064 cases treated at the City Hospital during the last year, were of cancer. The cost of maintaining the Hospital for the year was $11,471, of which amount $3,612 was contributed from the Ladies' Charity Fund for the payment of the board, in whole or in part, of in-patients in indigent circumstances.

Miscellany.

AN ASSOCIATION OF PHYSICIANS AND PATHOLOGISTS.

A LIMITED number of copies of the following circular have been sent out:

PHILADELPHIA, February 15, 1886.

DEAR DOCTOR: — In view of the undoubted advances which have everywhere followed in the different departments of medicine the formation of special societies devoted to their interests, and in view of the fact that each one of the natural divisions of medicine, except those of general medicine and pathology, is represented in this country by a special society, it has occurred to some members of the profession that a similar Association of Physicians and Pathologists is desirable.

Accordingly, two preliminary meetings were held in New York City on October 10th and December 29th, respectively, at which the matter was thoroughly discussed, and, after a general expression of opinion, it was finally decided: —

1. To form an Association of Physicians and Pathologists, of which the number of members shall be limited to one hundred (100).

2. To hold an annual meeting in the month of June, in the city of Washington.

3. To hold the first meeting on Thursday and Friday, the 16th and 17th of June, 1886.

The undersigned were appointed a Committee to notify those who were selected as original members, and we accordingly have the honor to cordially invite you to join this Association, and to take part in the proceedings of the first meeting in Washington, as above stated.

FRANCIS MINOT, Boston (Chairman of the Committee).
WILLIAM H. DRAPER, New York City.
WILLIAM PEPPER, Philadelphia.
R. PALMER HOWARD, Montreal, Canada.
ALFRED L. LOOMIS, New York City.
WILLIAM H. WELCH, Baltimore, Md.
FRANCIS DELAFIELD, New York City.
JAMES TYSON, 1506 Spruce St., Phila., Sec'y of the Com.

DIFFERENT PHYSIOLOGICAL SENSES FOR HEAT AND COLD.

IN connection with the researches of Prof. Hall and Dr. Donaldson of Johns Hopkins University, recently given in *Mind*, *Science* (Feb. 12) summarizes some interesting observations made by Mr. A. Herzen and published in the *Archiv für physiologie*[1] showing that the physiological sense of cold is different from that of heat. His attention was first directed to the subject by a simple incident, the verification of which may be readily made by any observer. Awakening one night he found one of his arms lying without the bed-clothes, "asleep." In touching it with the other hand, he perceived a distinct sensibility to warmth, while that of touch was gone. Bringing his arm, however, in contact with cold substances, he was surprised to find no sensation.

Pursuing the subject further, he produced artificially this condition of semi-paralysis by the compression of nerve-trunks, and by experimentation discovered that the sensibility to cold remained a short time after tactile impressions had disappeared, and that the sensibility to warmth remained much longer, but not quite as long as the power of detecting pain; also that the impressions of warmth require more time for transmission to the brain than those of cold, bearing, in fact, the same relations to each other as the sense of pain does to that of cold. These results were further supplemented by observations on a person with complete and permanent tactile anæsthesia of the legs, but in whom the sense of pain remained normal. The subject was able to distinguish quite well the differences in temperature between 150° F. and 81° F., which was the normal temperature of the surface of the leg. Below the latter temperature, however, no sensation was produced, not even by the contact of ice on the inner side of the thigh. Other cases showed the same peculiarities, in which, with the disappear-

[1] Ueber die spaltung des temperatursinnes in zwei gesonderte sinne, xxxviii. p. 93, December, 1885.

ance of tactile sensibility, the susceptibility to cold was also lost, while that to warmth yet remained.

Vivisection experiments upon cats and dogs lead the author to the following conclusions: 1. The so-called sense of heat and cold is composed in reality of two senses quite independent both anatomically and physiologically; 2. Observations on healthy and diseased subjects show that the sensations of heat and cold are transmitted through different nerves, by different routes, and to different brain-centres; 3. The gyrus sigmoideus contains the centre (or the centripetal branches leading thereto) of touch and cold perceptions; 4. These sense-perceptions are transmitted through the posterior columns of the spinal cord, while those of the senses of pain and warmth are conveyed through the gray substance.

Although the senses of cold and touch on the one hand, and heat and pain on the other, seem to be more nearly related, yet one cannot unite them, or consider the different perceptibilities of heat and cold mere modifications of those of touch and heat. The researches of Blix and others have demonstrated the existence of separated, isolated, irregularly distributed points upon the body, of which one may be only sensible to cold, another to warmth, and a third to touch. Doubtless most persons have noticed the different degrees of susceptibility of different parts of the body to heat and cold: the author points out striking examples of such.

AN INTERNATIONAL COMMITTEE ON A UNIFORM CLASSIFICATION OF MENTAL DISEASES.

THE *Société de Médecine Mentale*, of Belgium, in a paper by Professor Lefebvre, laid before the International Congress of Psychiatry and Neurology, which met at Antwerp in September, 1885, an address, inviting their attention to the subjects of the prevalence, causes, duration, and termination of insanity. Dr. Ramaer spoke at length on the classification of mental diseases. Both essays gave rise to free discussion, and an international committee was appointed to report at a future meeting on the classification of mental diseases, each member of the committee being expected to confer with the scientific society of his own country. There were eleven gentlemen appointed representing England, Germany, Austria, France, the Scandinavian countries, Russia, Holland, South America, North America, Switzerland, and Italy. The intention seemed to be to make the uniform classification of mental diseases a basis for further international statistics on insanity.

The New York Medico-Legal Society has appointed to assist the North American member of the international committee, Mr. Clark Bell, two committees, one of three, consisting of Dr. Pliny Earle, Dr. Alice Bennett, and Dr. Charles H. Hughes, and another of seven, composed of Dr. A. E. McDonald, Mr. Clark Bell, Dr. Jennie McCowen, Dr. Ira Russell, Dr. Stephen Smith, Dr. W. R. Birdsall, and Dr. T. H. Kellogg.

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 20, 1886.

Deaths reported 2,117: under five years of age 707; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 280, consumption 389, lung diseases 336, diphtheria and croup 142, typhoid fever 23, scarlet fever 28, whooping-cough 26, erysipelas 14, malarial fever 13, diarrhœal diseases 12, cerebro-spinal meningitis, nine, puerperal fever seven, measles six. From whooping-cough, New York 18, Brooklyn five, Philadelphia, Baltimore, and Chelsea one each. From erysipelas, New York four, Philadelphia and Boston three each, Brooklyn and Taunton two each. From malarial fever, New York seven, Brooklyn three, Baltimore, Charleston and Springfield one each. From diarrhœal diseases, New York six, New Orleans three, Boston two, Brooklyn one. From cerebro-spinal meningitis, New York four, Fall River two, Philadelphia, Baltimore and New Orleans one each. From New York two, Brooklyn, Baltimore, Charleston, Waltham and Newburyport one each. From measles Baltimore three, New York, Philadelphia and Holyoke one each.

In 109 cities and towns of Massachusetts, with a population of 1,250,326 (population of the State 1,941,465), the total death-rate for the week was 16.14 against 14.25 and 16.59 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending February 6th the death-rate was 22.2. Deaths reported 3,872: infants under one year of age 846; acute diseases of the respiratory organs (London) 479, whooping-cough 175, measles 76, scarlet fever 35, diarrhœa 35, fever 30, diphtheria 23, small-pox (Birkenhead and Liverpool one each) two.

The death-rates ranged from 13.4 in Brighton to 27.9 in Portsmouth; Birkenhead 20.8; Birmingham 19.9; Bradford 18.8; Hull 18.3; Leeds 21.9; Leicester 19.1; Liverpool 24.7; London 22.4; Manchester 27.1; Nottingham 24.9; Sheffield 21.3; Sunderland 24.6.

In Edinburgh 18.0; Dublin 33.7; Glasgow 26.2.

For the week ending February 6th in the Swiss towns, there were 34 deaths from consumption, lung diseases 30, diarrhœal diseases 10, diphtheria and croup seven, small-pox two, whooping-cough two, measles, scarlet fever and typhus each one.

The death-rates were: at Zurich 11.5; Geneva 20.2; Basle 26.6; Berne 15.0.

The meteorological record for week ending February 20, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Feb. 20, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING FEBRUARY 27, 1886.

CLARK, J. H., surgeon. Detached from the "Hartford," on the reporting of his relief, Medical Inspector Bradley.

BRADLEY, MICHAEL, medical inspector. Ordered by steamer of March 10th, from New York to Aspinwall, thence to Panama and to the "Hartford," as the relief of Surgeon J. H. Clark.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDING FEBRUARY 20, 1886.

AUSTIN, H. W., surgeon. To proceed to Richford, Vt., on special duty, February 8, 1886.

URQUHART, F. M., passed assistant surgeon. To proceed to Richmond, Va., for temporary duty, February 16, 1886.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, March 10th, at 7.45 o'clock. Papers: Dr. H. O. Marcy, "Photo-Micrographs of Bacteria; Projected upon the Screen." Dr. W. N. Bullard, "Chronic Tea-Poisoning."

F. I. KNIGHT, M.D., *Chairman.*
ALBERT N. BLODGETT, *Secretary*, 138 Boylston St.

PROVIDENCE MEDICAL ASSOCIATION. — The Annual Meeting of the Providence Medical Association was held in the Medical Library, on Monday evening, March 1st, and officers for the ensuing year elected as follows: President, J. W. Mitchell; Vice-President, C. H. Leonard; Secretary, Herbert Terry; Treasurer, G. T. Swarts; Standing Committee, H. G. Miller, G. D. Hersey, G. W. Porter, R. H. Carver, W. R. White; Committee on the Reading Room, G. D. Hersey, G. W. Porter, Eugene Kingman.

DEATH.

Died in Lowell, Mass., February 25, 1886, Joseph Haven Smith, M.D., M.M.S.S., aged eighty years.

BOOKS AND PAMPHLETS RECEIVED.

The Methods of Bacteriological Investigations. By Dr. Ferdinand Hueppe. Translated by Hermann M. Biggs, M.D. Illustrated by Thirty-one Wood-cuts. New York: D. Appleton & Co. 1886.

Transactions of the State Medical Society of Wisconsin, 1885.

Thirty-Eighth Annual Report of the Trustees of the Massachusetts School for the Feeble Minded at South Boston. For the Year ending September 30, 1885. (Public Document, No. 28.)

Eleventh Annual Report of the Boston Womans' Christian Temperance Union. For the Year ending October, 1885. Boston, 1886.

Mutual Protection against Blackmail. By E. J. Doering, M.D., of Chicago. (Reprinted from Journal of American Medical Association, January 30, 1886.)

The Climate of South Central Florida, Especially for the Pulmonary Diseases for Women and Children. By J. M. Keating, M.D., of Philadelphia. (Reprinted from the New York Medical Journal for January 23, 1886.)

Priced and Illustrated Catalogue of Ophthalmological Instruments, Spectacles and Eye Glasses. By James W. Queen & Co. Philadelphia.

Clinical Cases from Dr. Sée's Wards. By Oswald Browne M.B., and D'Arcy Power, M.B. A Case of Locomotor Ataxy, Associated with Perforating Ulcer of the Foot. (Reprint from St. Bartholomew's Hospital Reports, Vol. xviii.)

Three Specimens of Encysted Hernia, etc. By D'Arcy Power. (Reprint from Transactions of the Pathological Society of London for 1885.)

A New Operation for the Alleviation of Persistent Deafness. By Wm. H. Bates, M.D. New York. (Reprinted from Medical Record, January 23, 1886.)

Puerperal Pyrexia. By George P. Andrews, M.D. (Reprint from American Lancet, January, 1886.)

The Treatment of Vomiting with Large Doses of Oxalate of Cerium. By W. R. Chittick, M.D. (Reprint from Detroit Lancet, September, 1885.)

Practical Human Anatomy. A Working Guide for Students of Medicine and a Ready Reference for Surgeons and Physicians. By Faneuil D. Weisse, M.D. Illustrated by 222 lettered plates containing 321 figures. New York: Wm. Wood & Co. 1886.

TWO CASES OF CEREBRAL TUMOR WITH AUTOPSY.[1]

BY E. B. LANE, M.D., OF BOSTON.

James M., thirty-seven years old, was admitted to the Lunatic Hospital August 3, 1885. Married. Policeman. Was born in Ireland. Very little is known of his family, since none of his relatives are in this country. Used alcohol daily, would occasionally drink more than he ought, but never incapacitated himself for duty on the Boston police force.

Is not known to have had rheumatism nor any severe illness previous to last January. No specific history could be obtained.

In January, 1885, fell on the street, becoming unconscious and remaining so for half an hour. Became conscious soon after reaching home, but for more than a week his speech was thick and he swallowed with difficulty. No other paralysis was known. Went on duty a month later. Then his speech was much improved, but not quite clear. Continued to perform his duties as usual until May, when he had a second attack, this time in the house. Fell but did not become unconscious. He got up unassisted and sat down. It was found that his right side was affected, the hand and leg of that side being weak but not completely paralyzed. He was able to walk. His speech was not affected nor his ability to swallow impaired. No facial paralysis was noticed. He had no headache either before nor after this attack. Slept well and ate well. Regained the use of his limbs to a certain extent but could not light a match with his right hand, could write, but his hand was tremulous. Returned to patrol duty in two weeks and remained on duty until the middle of July, when he had an attack of vertigo while on the street. Was sent home in a horse-car. Felt ill and stayed at home until admitted to the hospital a fortnight later. After the second attack (in May) became irritable, and memory failed somewhat. Became suspicious that men talked with his wife, and that she had had visitors.

During the last two weeks at home his mental condition degenerated rapidly. Memory grew weaker. He was anxious to go to the Station-house and would become angry, though not violent, when restrained. Delusions of suspicion developed. Thought there were men concealed in the house and he procured a pistol and billy to defend his wife.

On admission, was seen to be a well-developed man of medium size. Too dull to respond to questions. Was able to get about and uses his hands fairly well. Right eyelid drooped. Pupils were equal, tongue protruded to right (probably accidental, as it afterward came out straight) not retracted. Eats when fed but will not feed himself. Will not stay in bed and soils the floor. Pulse 60. Patellæ reflex present. No enlarged glands. Denied syphilis. Eyes examined. Nothing unusual seen beyond a fulness of the veins of the fundus.

During the first week at the hospital, condition did not change much. Would answer simple questions. Had considerable difficulty in swallowing. About this time he became comatose with a temperature of 102.6 and respirations 44. Left pupil dilated. He rallied to his former condition in the house. He then gradually improved mentally[2] until at the end of the second week he knew his wife and conversed with her and signed some documents. But at no time did he realize where he was nor avoid wetting his bed. When asked to put out his tongue would do so after waiting nearly a minute. Memory was very weak, would not know his room but would wander about, upsetting furniture, etc. After being in hospital a month was able to be dressed, saw an old acquaintance and chatted with him. Told him that he had been on his beat that day. Difficulty in swallowing almost entirely disappeared and he ate heartily. At this time patellar reflex was found to be excessive and ankle clonus present. Said he was "first-rate." About the middle of September (six weeks after admission) rapidly grew dull, swallowed liquid with difficulty. In a few days febrile reaction appeared. Was very obstinate, resisting everything done for him, fumbled the bed clothes and handled his genitals constantly. Temperature varied from 99 to 103. Respiration persisted rapid, gradually rising from 30 to 50. Was very helpless, could scarcely swallow and was so dull he would not speak, and in eighteen days from the onset of the stuporous condition died.

Autopsy twenty hours after death by Dr. Gannett.

Ratio of head to body and cranium to face normal.

Calvaria thin. The dura everywhere translucent and the sinuses contained dark fluid blood. The pia slightly opaque about the convexities. Its meshes contained a small amount of clear fluid. The brain filled the cavity of the skull and weighed 1,402 grms. The vessels at the base and in the fissure of Sylvius showed nothing remarkable. The pia anterior to the optic commissure showed a slight snuff-colored appearance and on section showed several opaque grayish-yellow globular nodules varying from one to three mm. in diameter and each surrounded by a grayish-red translucent tissue for a distance of three to four mm. These were directly continuous with the pia. On the under surface of the right frontal lobe, adjacent to the pia was a nodule the size and shape of an almond, except not quite so long, having an opaque grayish-yellow centre, the size of a large pea and surrounded by a reddish-gray translucent material like that already described.

In the lowest portion of the left temporal lobe at anterior extremity were several yellowish nodules about 2 mm. in diameter, surrounded by a reddish-gray translucent tissue. At the junction of the anterior and middle thirds of corpus callosum and on the adjoining convolution in the anterior fissure were a series of yellow nodules of two or three mm. in diameter arranged antero-posteriorly forming a line about four cm. in length. These were in turn surrounded by a similar reddish-gray translucent material.

The lateral and fourth ventricles showed in the ependyma numerous fine granules presenting a warty appearance. The floor of the left lateral ventricle over the basal ganglia showed two depressions about twenty mm. in diameter.

On section in the left *nucleus caudatus* and in the left *thalamus opticus* were cavities the size of small filberts, formed by a meshwork of fine lines and containing a snuff-brown fluid. In the posterior portion of the right *thalamus opticus* were two cavities each about

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, January 13, 1886.

[2] His mental condition was that of contentment. Speech was that of a general paralytic. No delusions of grandeur expressed.

the size of filbert meats and presenting the same characteristics as those described.

The section of the hemispheres, pons, medulla and cerebellum showed no appearances worthy of special note. The pia everywhere readily separated from the brain substance. Heart and pericardium showed nothing worthy of note. Examination of the other organs showed little of interest beyond diffuse bronchitis and tracheitis, chronic pleurisy and a nodule in the mesentry. There was a scar on the penis.

Diagnosis of lesions found in the brain. Chronic lepto-meningitis and œdema of the pia, each to a slight degree only. Multiple gummata. So-called "apoplectic cysts" of the basal ganglia. Chronic ependymitis.

Mary J., sixty-four years old, of American parentage, a cloak-room attendant, was admitted to the Boston Lunatic Hospital, September 3, 1885. With her was sent the statement that she had been hemiplegic for nine days, that she was at times incoherent and confused, was helpless and needed hospital care. After her death the following history was obtained.

Family history unknown. Seventeen months ago her husband died and his loss caused the patient much grief and worriment. Since death of husband she has been in very straitened circumstances.

For the past six months has complained of severe headache and loss of memory, and when alone in her room would continually talk aloud to herself. Appetite was good. When not mindful of her loss was as cheerful as ever. Continued to attend to her duties in a cloak room, and to her household duties until eight or nine days before admission. No serious sickness was suspected until she was found one morning to have right sided hemiplegia, to be almost speechless as well as perfectly helpless, having been apparently as well as usual the day before.

On admission to the hospital was seen to be a very large well nourished woman. She was helpless, having right sided hemiplegia. Was very dull, but would answer a few simple questions.

For four days after admission was dull and gave unintelligible answers. Took a small amount of liquid food when it was placed in her mouth. Could not eat, and swallowed liquids with difficulty. Was noticed to call things by wrong names.

At the end of this time she became brighter, was not quite as helpless, could swallow a little better and could speak more distinctly. It was now seen that she was partially amnesic, more accurately speaking, she was almost totally unable to recall names. It was usually impossible for her to name objects. She could not even recall her husband's name. Was aware of her defect and seemed much annoyed by it. When asked to name a bunch of keys she said "I cannot," then made an effort and pronounced "boots" and laughed at her failure. Was then told to say "keys." She made another effort and said "that is right, skewers," and laughed again. But on being prompted a second time she pronounced "keys" properly.

Physical examination showed the right sided hemiplegia to persist, mouth was drawn to the left, tongue was protruded straight, however. Left eye was turned in, showing probable paralysis of the sixth nerve on that side from pressure. Pupils were even. Plantar reflex present. Ophthalmoscopic examination was impossible. Remained in this condition, conscious, but dull and listless for two days. Did not ask where she was nor seem disturbed by her new surroundings. She continually complained of thirst. She became more dull on the ninth day, and on the morning of the tenth was found comatose. Had been vomiting. Made automatic movement with left hand only. Pupils were much contracted and pulse was 96, temperature 101.5 (P.M.) Coma lasted only twenty-four hours and during the following day she gradually grew brighter and was as well as before the attack. Condition of side, however, did not improve.

She gradually grew more intelligent and for a short time knew where she was, but probably did not realize the significance of it. Remarked that she must be a difficult patient to care for she was so heavy and helpless. She became more restless and would kick the bedclothes off with left leg. Could use both hands a little. Required to be watched or she would lie uncovered. Gave no reason for it. Was at this time asked if she were hungry and she replied "yes," was asked if she were thirsty and she said "yes," and to test the truth of her statement was given bread and milk. Declined it saying she wanted something "brighter." She seemed aware she had not said what she meant. When asked if she would prefer water seemed pleased and assented. At another time asked for "fire," and then shook her head. When asked if she meant water said "yes, fire," and laughed at her blunder. When "water" was slowly pronounced she repeated "w-water."

Memory was much impaired, she could not remember whether she had eaten two hours after doing so.

On the seventeenth day, and a week after the brief period of coma, the patient grew more dull and helpless. Would not swallow liquids and gradually became comatose, sweating profusely and occasionally vomiting a greenish watery fluid. Pulse was strong, but uneven and rapid. Respiration was labored and noisy, tracheal râles persisting until death. She continued in this coma five days, death being hourly expected. Died on twenty-third day.

Autopsy was made twenty-two hours after death by Dr. Gannett.

Nothing unusual was observed about the calvaria or dura. Sinuses contained soft coagula. The convolutions of the brain flattened and sulci obliterated: surface of pia dry.

The brain completely filled the cavity of the skull and weighed 1,550 grms. At a point in the left fissure of Sylvius where the middle cerebral gives off its numerous branches, was a dilatation the size of a pea.

At a corresponding position in the right side was a parietal dilatation the size of a pin's head.

In the basilar artery was an opaque yellow patch in the intima about three mm. in diameter. The right lateral and fourth ventricles showed nothing remarkable.

The floor of the posterior portion of the left lateral ventricle was elevated, rounded and quite tense to the finger. On section of the hemispheres there was found in the white matter of the left hemisphere posteriorly a rather firm opaque grayish yellow nodule, the size and shape of a medium sized peach, showing on section here and there spaces filled with a thin cream-like fluid. The brain substance on the periphery of the nodule for a distance outward of about four mm., showed to a very slight degree a punctate appearance. The white matter lying just beneath the nodule was of soft consistency and grayish-white color. The white matter in general was rather pale, surface of usual degree of moisture, the cortex not remarkable.

Section of the basal ganglia, pons, medulla, and cerebellum showed no appearances worthy of special note. . . .

Examination of the other organs revealed nothing of interest beyond a large cyst occupying the upper third of the right kidney, pelvic calculi, and two firm gray nodules the size of a pea in the wall of the uterus. A pedunculated polypoid tumor in the cavity of uterus.

Microscopic examination of the tumor has been begun by Dr. Gannett, but owing to the hardening not being yet completed he is unable to give a definite opinion. He has kindly consented to offer the *probable* diagnosis of *vascular glio-sarcoma.*

Summary. In the first case, we have a young man with cerebral syphilis resulting in paretic dementia. From the onset of mental derangement the course of the disease was unusually rapid. The hemiplegia and the mental condition of hebetude and delusions cannot be said to follow the presence of the gummatous tumors as the hæmorrhage in the candate nucleus and the lepto meningitis are the lesions more commonly associated with such symptoms. No especial set of symptoms can be referred to any of the tumors.

The second case was remarkable in the fact that a large tumor must have been gradually developing in the mass of the cerebrum causing for a long time only minor symptoms and finally causing such severe and fatal symptoms. A woman able to do her daily work, neither general nor mental health being sufficiently impaired to attract attention, suddenly becomes comatose and hemiplegic. She recovers consciousness and suffers two more relapses of coma and dies. During the intervals of consciousness she is seen to be suffering from a partial amnesia. Amnesia (oftener partial than complete) has been found to be associated in cases reported by Werwicks and others, with lesions in the occipital lobe. The question might arise as to the possibility of there being an aneurismed dilatation causing the symptoms. This is hardly tenable when we consider the great extent of the pressure required to cause both hemiplegia and amnesia. The vascular changes in the tumor must explain the suddenness of symptoms.

Ferrier, Pitres, Ross, Gull, Rodocalat, March, Lester, et al., report tumors or abscesses of occipital lobe. Werwicks, Dreschfeld, Hissenberg "aphasia" following tumor in occipital lobe.

ENLARGED CERVICAL GLANDS.[1]

BY HERMAN F. VICKERY, M. D., OF BOSTON.

THE object of this paper is to arrive at definite and well-grounded opinions as to the treatment of what is sometimes called "scrofulous neck." These cases present enlarged lymphatic glands in the neck, causing little inflammatory disturbance or pain as a rule, but very chronic and tending to break down into cheesy pus. Exceptionally, complete resolution takes place; more often, fibrosis or calcification; but, in the great majority of cases, sooner or later, arises an abscess which discharges through a sinus, the sinus emitting pus more or less constantly until the entire gland has been thus expelled. Although there is not much suffering, yet the tediousness of these cases, which may persist for years, the unsightly appearances occasioned both by the glands and sinuses and by the scars they leave behind, and above all certain dangers hereafter to be more fully discussed, render it desirable that the best possible treatment should be employed for them.

We find the disease prone to attack children much rather than adults, although even old age is not absolutely exempt. All debilitating, hereditary, or hygienic conditions predispose to it: its chief victims therefore, are the children of the poor and ignorant, or of consumptive or syphilitic parents. Overcrowding, lack of sunlight, insufficient and improper food, exposure to cold and wet, all promote its occurrence. Out of one hundred and seventy-two children who entered a workhouse in Kent, England, healthy, all but three came to have enlarged glands. The exciting causes are very numerous, comprising such lesions of the mucous membranes as ozæna, stomatitis, tonsillitis, pharyngitis, laryngitis, otitis, and conjunctivitis. It may follow chronic eczematous processes in the scalp or face. It frequently arises after scarlet fever and measles, and may be excited by dentition or by trauma. It is characteristic of this form of adenitis that, although supposed to be invariably secondary, its extent and persistence frequently far exceed those of the primary lesion. It is often impossible to determine what did give rise to the glandular disorder.

In early stages, the enlarged glands are freely movable upon the underlying tissues and underneath the skin. They are smooth in surface, of uniform density, and more or less spherical. It is seldom that a solitary gland is swollen: usually two or more are affected. The affection is not essentially symmetrical: it may be bilateral. After continuing a variable length of time with but little change, the gland may, as has been said, be absorbed. Such a result is especially likely at puberty. The rule, however, is that the tissues undergo what is called a "cheesy" degeneration. This can usually be recognized during life by the nodular surface of the gland, its presenting spots of softening or fluctuation, and its adherence to the skin as well as to neighboring glands, if they also are enlarged. A rare termination for this cheesy transformation is spontaneous desiccation and calcification. Almost always there is gradually increasing suppuration, abscess formation, and external discharge through the adherent skin. About the histological changes, I wish merely to state what seems essential to forming a just view of the dangers and treatment of the disease. Schüppel of Tübingen published in 1871 a book on "Tuberculosis of the Lymph-Glands," in which he shows that a large proportion of what are called "scrofulous" glands — although not all — present the microscopic characteristics of tubercle, that is, one or more giant cells surrounded by epithelioid cells and lymph corpuscles, the whole supported by a fine recticulum. Klebs produced, by the inoculation of tuberculous matter, a disease of the lymph glands exactly like scrofulous infiltration. Koch reported, in 1884, that he had examined twenty-one cases of tuberculous glands (meaning such glands as presented epithelioid cells, grouped in foci, and accompanied by more or less numerous giant cells), and that he invariably found bacilli tuberculosis in them. There were indeed other enlarged glands, in part softened and dotted with minute abscesses, but with no epithelioid nor giant cells, in which he found no bacilli. From the submaxillary gland of a scrofulous boy, he obtained pure cultures of the specific tuberculous bacilli. Dr. Hippolyte Martin also produced a series of

[1] Read before the section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, January 13, 1886.

cases of general tuberculosis in guinea-pigs, starting from the inoculation of pus taken *post-mortem* from the "firmly encased submaxilary gland of a child, who had died of measles and broncho-pneumonia, without any trace of tubercular disease, but with well-marked clinical characteristics of scrofula." It may therefore be affirmed of enlarged cervical glands, such as are ordinarily called scrofulous, that certainly a large proportion, and probably a large majority, are really tuberculous.

As already stated, the existence of scrofulous lymphatic glands usually implies that the general health has been impaired. The local disturbance is seldom very annoying. The condition is often discovered by accident. Occasionally there is some pain and tenderness, particularly if suppuration is taking place. By its mechanical pressure, a gland, or a collection of glands matted together, may give rise to compression of the carotid or jugular, the trachea or œsophagus, the recurrent laryngeal, symphathetic or vagus nerves. Epistaxis is sometimes caused by them, and even fatal suffocation.

It is seldom that diagnosis is difficult. Acquired syphilis may cause induration of the cervical glands, but the enlargement is less, the tendency to cheesy degeneration is slight, and we should find other venereal symptoms. A simple adenitis, such as might, for example, follow traumatism, is more acute. It exhibits more inflammation and either resolves or suppurates much sooner than a scrofulous gland. Pseudo-leukæmic glandular enlargements are more or less universal throughout the body, that is, in the axillæ and groins and at other joints, they grow more rapidly, do not break down, and are accompanied by marked anæmia and debility. Glanders and farcy could hardly be mistaken for mere scrofula if the physician exercised any care whatever; and the same might be said of bronchocele. Cystic and other tumors may occur in this region, but are comparatively rare, and their differential diagnosis can be learned in works on surgery.

"The scrofulous patient," says Allbutt, writing on the treatment of scrofulous neck, "runs three risks in the continuance of his local malady over and above his faulty inheritance, namely, first, a tedious local disease followed by a peculiarly unwelcome disfigurement; secondly the fear of deterioration of his general health thereby, such that his best years of adolescence are spoiled and his entrance into manhood thwarted and weakened; thirdly, an inoculation of the system with elements which favor the development of more general tuberculosis."

In the early stages it is quite possible that a gland may be absorbed if the general health be built up. Local applications may also promote the same result; but we shall revert to this point under treatment. When once nodulation, softening and adhesions have begun, the cheesy process is under way, and it seldom ceases before the gland is totally necrosed and discharged. A fibrous or calcareous transformation of the gland is, however, possible, as is also absorption even now. A further and more important consideration is the effect upon the general health, if the glands are tuberculous. Friedländer in his familiar lecture on "Local Tuberculosis" states that although the process is malignant it is not apt to become diffuse. Out of 332 cases of phthisis, Philips found, *post-mortem*, "scrofulous scars" in but seven. Again, out of 1,078 autopsies of consumptives less than one per cent. showed evidence of cervical gland disease. Says Treves, in his work on "Scrofula and its Gland Diseases," "while scrofula and phthisis are manifestations of the same morbid process, I am nevertheless convinced that phthisis is by no means common in the scrofulous, and that the bulk of such patients do not die of pulmonary consumption." And as to the danger of acute miliary tuberculosis, Treves does not think it very great, although he would not be utterly indifferent to it. On the other hand, Rindfleisch believes that "Tuberculosis hardly ever appears except in scrofulous persons." Lynch affirms that "The products of decay resulting from scrofulous processes may enter the circulation and directly produce the tuberculous dyscrasia." Further remarks about prognosis will be made incidentally under Treatment, which is the next and final topic.

The first indication to be met is of course to allay all causative disorders, such as eczema, rhinitis, pharyngitis, and the like. The general health next demands attention. In the first place it is usually depraved. Secondly, if the patient be in a state which offers the bacilli tuberculosis a favorable nidus so far as the lymph glands are concerned, why may we not justly fear that predisposition to tuberculosis pulmonum also exists? Either ground is sufficient basis for vigorous tonic treatment. Fresh air should be obtained for the patient, either at the seashore or in the mountains or in the country. For dwellers near the coast it would seem more natural to choose the interior. Sunlight, moderate exercise, simple but nutritious and abundant food, salt-water baths, and such analeptics as cod-liver oil, iron, arsenic or iodine, all these should be simultaneously brought to bear upon the case.

If glands are already cheesy we may be tolerably certain that a lingering, disagreeable and disfiguring process will go on for months and perhaps years, unless the necrotic tissues are removed by operation. Experience has proved only too clearly the inefficiency of external applications; while surgical removal has been found to be very satisfactory and comparatively easy. For example, Billroth, Treves, Fagan, of Belfast, and Teale, of Leeds, all express themselves as pleased with the results of extirpation.

About the treatment of cases still in the first stage there seems to be more room for difference of opinion. Let us make sure before we form our own, what we would like to obtain for a local result. Friedländer makes the following therapeutic deductions at the end of his lecture already referred to: it is desirable to remove tubercles where it can be done without danger, because (1) they are fated to destruction, and until they are removed recovery cannot be perfect. And (2) by such removal we destroy a source of at least local infection. On the other hand, he proceeds to say, we should only very exceptionally undertake any serious operations which cripple or deform the patient, just on account of local tuberculosis: because (1) constitutional infection is not inevitable, and (2) spontaneous recovery is possible. Schüppel quotes with warm approval the dictum of Virchow that "it is certainly justifiable to remove as early as possible such tuberculous organs as can be easily reached. "If operation seems impossible or undesirable then we should at least hasten suppuration and free discharge." Treves in discussing treatment declares, "Out of the enormous number of patients who present caseous deposits in their bodies the percentage of those who fall victims to

diffused tubercular disease is so very small that the probability of that disease may be put out of the question. I think also," he continues, "that the argument advanced by Ruehle in favor of removing glands on the plea that such removal may prevent phthisis is unworthy of consideration in discussing this mode of treatment," that is, by excision. These opinions seem to differ considerably, but certain deductions can be made from them. There is an acknowledged possibility of constitutional infection from strumous glands. The virus, if it becomes thus generalized, can only do so by way of absorption. It is then pertinent to inquire, Why endeavor by external applications to promote resolution of enlarged cervical glands?

Very likely we all breathe daily into our lungs the bacilli of tubercle and yet do not become consumptive, because presumably our bodily condition is such as repels the invader. But the sufferer from tuberculosis of the cervical glands might as has been seen, naturally be supposed to exhibit a predisposition to tubercle. If by invigorating his system we get him into such a state that Nature of her own accord absorbs the disorganized tissues, we may be content; for she probably will do it with impunity. Experience shows that this is often the case. It does not, however, commend itself to my judgment to seek, even in the first stages of the malady, by local irritation, such as the application of various forms of iodine or by blisters or electricity, as some recommend, to excite an artificial resolution, if I may so express myself. It may be added that the attempt is often futile. If *general* stimulation fails, then we should resort to extirpation.

The only occasion which seems to me to call for local application is where there are pain, heat and swelling, and as yet no certainty that suppuration has taken place. Such glands should be treated with a cooling wash until they either abate or else present clear signs of pus.

By first improving the general health there will little time be lost. Possibly some or all of the glands may be absorbed. If not, operation will take place under much more favorable auspices.

Glands which are in the first stage and freely movable can be quite readily cut out. The incision should not be very long. Violent tearing of the surrounding tissues besides other things brings danger of troublesome periadenitis. The cheesy glands (which are nodulated or have perhaps suppurated and are fixed to the skin and to each other) are usually best extirpated with a spoon. Treves has found the thermo-cautery very serviceable. In cases where a subcutaneous abscess has formed it is often a much more ready than satisfactory method to make a simple incision. Pus should indeed be evacuated without delay; but a careful search will quite frequently discover a sinus leading from this superficial abscess to a cheesy gland deeper in, which itself must be eradicated. Teale praises Bigelow's sinus dilator for such operations. Antiseptic precautions are advisable, and iodoform makes a good dressing. Drainage is usually necessary. Healing is promoted by obtaining rest for the parts as by a leather or gutta-percha stock, outside the bandages.

The different manifestations of scrofula are said to be somewhat antagonistic to each other, so that "the particular scrofulous malady any given patient presents would appear to protect him from any other outcome of the disease for at least the time being." This need not, however, prevent operation, for there is practically no danger that the eradication of scrofulous glands will indirectly excite caries or tumor albus and the like elsewhere.

SOME OBSERVATIONS ON HEALTH RESORTS.[1]

BY E. O. OTIS, M.D., OF BOSTON.

IT is not with the expectation of presenting anything new upon the subject of health resorts that I write these few notes. But rather with the hope that possibly I may render some aid, by means of the following suggestions and record of personal observations, limited though they may be, to the family physician who is called upon, as he unfortunately so often is, in this climate, to recommend a proper resort to his patients suffering from pulmonary trouble, for they compose the majority of those who seek a new clime.

The whole subject of climatic cure is a many-sided one, and there are many and diverse opinions as to what constitutes a suitable resort for those with delicate or diseased lungs. I have only to refer to the excellent paper of Dr. Harold Williams, in a recent number of this JOURNAL, to show the variety and conflict of opinions which exist upon this subject. The general fact, however, remains that thousands have had their lives prolonged or saved by a timely resort to some one of the many places in this country, more favored by nature as to climate than this bleak New England coast.

I am not a partisan of any special portion of the country or place, as a universal elysium for all those afflicted with lung trouble. On the contrary, I believe that each individual case should be carefully considered in all its aspects, and be sent to that place and climate which seems best to meet its own especial needs and requirements.

One person has little vitality and is always pinched with the cold; such a one obviously will do better in a moderately warm climate, like southern California or Florida. Another case will endure a certain degree of cold, and will thrive in a locality of lower temperature, like Colorado or Asheville. Again, the digestion may be at fault, and it is of primary importance that a place should be selected where a good table can be depended upon even if something has to be sacrificed as to the climate. Moreover, the mental condition and temperament must not be disregarded, and the kind of life the patient has been leading. One person requires much diversion, and would be wretched in a quiet, secluded place, but contented and happy in a more lively one, like St. Augustine, for instance.

Companionship is also an important element, and with pleasant, genial companions, one will often make greater gain in a less favored locality, than with the lack of them in one more nearly approaching the ideal climate. The opportunities which different resorts offer for varieties of exercise are not to be lost sight of, as well as the favorite form of exercise of the patient. Happy and fortunate is the consumptive, as well as any other man, who has a hobby which will give him exercise in the open air, be it fishing, gunning, rowing, or horse-back riding. I believe that the cause of many of the unfavorable results in cases which have been sent to health resorts of acknowledged worth, is the neglect of carefully considering all these factors.

Of course, it goes without saying, that due attention

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, January 13, 1886.

should be given to the hygienic condition of the locality determined upon, and also, that the fundamental principles of all health resorts are to be borne in mind, namely: pure air, dry soil, and abundant sunshine. Elevation, dryness, and equability, are often, I believe, of secondary importance, and are to be taken into account rather when the requirements of the individual case are being considered.

There should be at hand, also, in every health resort, a reliable physician, with whom, if necessary, the home physician can communicate concerning his patient, and who being familiar with all the conditions of the place and climate, can give such advice as one should have upon taking up his residence at the resort.

I am of the conviction, as I believe all are who have given much attention to the matter of climate, that the best results are obtained by as long a continuous residence as possible in the place and climate which has been found to suit the case. It takes a long time to become acclimated, if the change is at all radical, as from a cold to a warm climate, or from a low to a high elevation, and after that comes the benefit and improvement, and so long as that continues, the better it is to remain in the chosen resort.

Still there are many whose conditions and circumstances are such that the stay away must be limited, and the number of places from which to choose restricted. In order, then, that the most good may be accomplished from the time allowed, all the greater care must be given in the selection of the resort from among the ones possible to the case in question. Indeed, so many points have to be thought of in choosing a new home for the man of weak lungs, that I have almost come to the conclusion that no physician has any right to advise a patient to go to this place or that, unless he has first visited it himself and thoroughly investigated its advantages and defects. Recently, a young lawyer came to me and related his experience in being sent to a health resort. After it was determined, from the condition of his lungs, that he must go away, the advice as to a new climate was something in this wise: "Some say this place is good; others that; I know nothing of any of them. You may find the Tennessee Mountains of benefit, but I know nothing about them; have never been there; you can go and try them." So he went, and after numerous vicissitudes, he fell to living a complete out-door life, much of the time on horse-back, and came home apparently well, and has remained so for several years. Such hap-hazard advice, however, will not always have such fortunate results.

"Happy the patient," says Youmans,[2] in a recent article on "Thomasville as a Winter Resort," "advised to change his climate when the physician knows enough to give him intelligent instruction as to whither he shall proceed. Does he need a mild or a high temperature? a damp and relaxing, or a dry and bracing air? an inland location or the seaside? a valley or a mountain? Should he try Bermuda or Aiken, or Nassau or St. Augustine, or Asheville, or any of the score of resorts recommended for pulmonary invalids? If the doctor settles the point, it is well; if not, the patient must take his chances, and do the best he can to settle it for himself." Going on to relate his own experience, he says: — "With lungs badly out of order, everybody said I must escape the severities of a New York winter by going somewhere. I advised with several eminent pulmonary experts, who agreed that it might be a good thing to get away, but did not seem to think it made much difference where I went."

If specialists continue to multiply, perhaps in the future we shall have the specialist on climate. One who has visited the different health resorts and made careful observations, not only as to any particular climate, but of all the accessories of the place — food, sanitary condition, means of exercise and amusement, manner of reaching it, and so on; and who, moreover, will give an unbiased opinion, instead of the half truthful, exaggerated reports which local partisans give of the places they are personally interested in. In a pamphlet before me, just received from Thomasville, Ga., I quote the following as illustrative of this exaggeration: "The fact is well recognized that a damp atmosphere is what a sufferer from pulmonary trouble should avoid, and it follows, that to obtain the greatest amount of good effects from the presence of the fragrant pines, the breezes that waft the balsamic odors abroad must be dry, and themselves inodorous. In order that these conditions be fulfiled, it is essential that large quantities of water be absent, and the surface of the country be high and rolling. A fulfilment of these conditions is impossible in Florida, surrounded as the State is, on three sides by the ocean, with its land surface but a few feet above the level, a dreary waste of interminable swamp, intersected by sluggish streams and marshy lakes. Perched on her elevated position, Thomasville can lay claim to the advantages of a dry climate and thorough drainage, and her claims have secured the recognition of the most eminent physicians of the country who have made pulmonary troubles a study."

Again, in an article entitled "Marion County, Florida: An Ideal Winter Climate," by Dr. Maxwell, of Ocala, published in the *Medical News* of December 19, 1885, the author, among a number of very loose statements, makes this assertion: "It is capable of demonstration . . . that Florida possesses the essentials (of an ideal winter climate), in a higher degree than any country now known;" and as a part of this demonstration, he introduces a table of mean relative humidity, compiled by Dr. Kenworthy, from the inevitable Signal Service Reports, which shows, he says, "that Jacksonville, in the matter of dryness of air, compares favorably with the popular resorts in all parts of the world;" the table given, containing the names of thirteen places only, three being in Minnesota, three in Florida, two in France, and one each in Nassau, New Jersey, Georgia, Dakota, and Massachusetts. If the Doctor had included Denver, for instance, in his list, he would have found its relative humidity some seventeen points lower than that of Jacksonville.

I will now give some notes and bits of information upon a few health resorts I have visited in the South and elsewhere, and I trust I shall be pardoned if I seem to give some petty details, even to the noting of boarding-houses; for such information is often of much assistance in settling the perplexing question of a new home and climate.

The Southern resorts can roughly be divided into those of the coast, interior, and mountains, and with the exception of the latter regions, are generally regarded as winter homes for invalids; but the rule of continuous residence, before mentioned, will hold good, I believe, even of many of these Southern localities. The mountainous regions, embracing the Alleghany,

[2] Popular Science Monthly, December, 1885, page 188.

Blue Ridge, and Cumberland Ranges, are considered more appropriate for the milder portions of the year, but here, again, I would advocate the above rule for, at least, portions as far south as Asheville, unless the idiosyncrasy and condition of the patient were such as to forbid a moderately cold climate.

Of the coast resorts, places on the East or West side of the Peninsula of Florida are, perhaps, more generally selected, and whether the Atlantic or Gulf of Mexico shore is the more favorable, seems to be a matter of opinion. As the prevailing winds are East, it is said that the Atlantic coast gets the purer air direct from the ocean, while it reaches the Gulf coast after blowing over the peninsula, and is, in consequence, more or less vitiated. Of course, the climate of all sea-coast resorts is a more or less moist one, which, in adapting a climate to the individual case, is a factor to be considered.

One fact I desire to emphasize, and I might as well mention it here, namely, that, in my experience, it is exceedingly difficult to obtain good food in the South. The meat and bread are poor, as a rule, and the coffee, with few exceptions, execrable, and from the fact that there is very little grazing, the milk is poor, if, indeed, it can be obtained at all. The houses where good board is obtained are generally kept by Northern people.

On the Atlantic coast, St. Augustine is the best-known resort, and it has much to recommend it. The soil is sandy, and the days, so far as my experience goes, are generally sunny and delightful. The mean temperature is 58° in the winter, and 68° in the spring. The number of clear days for the whole year is said to be 235, which I should very much doubt. Artesian wells have recently been sunk, and the city is now supplied with good water in place of the surface water formerly used. It is an attractive place on account of its picturesque, quaint architecture, the old fort, sea wall, and barracks, and the presence of a military band adds much to the pleasure and entertainment of the exile. There is also good sailing and pleasant water excursions.

If I may be allowed to give a couple of names, I will say that any one who can obtain accommodations at Miss Hasseltine's on St. George Street, and have for his medical adviser Dr. Adams, will be well cared for. As to malaria, I have not much doubt as to its existence pretty much all over the South, but I saw very little evidence of it in St. Augustine.

If one desires to go still farther south on the Atlantic coast, the little town of Daytona on the Halifax river, was highly extolled to me for its agreeable climate, by a resident of the place.

Going over to the Gulf side, I will speak of Tampa, reached by railroad direct from Sanford. In itself, it is not very attractive, the streets being very sandy, which renders locomotion uncomfortable. The bay, however, is delightful, and the excursions upon it, and up the Manatee River, and to Egmont Key are charming. So far as one's sensations go, the air seems delicious.

Bordentown, on the Manatee river seemed to be a quiet, pleasant retreat. I believe it is on the Gulf coast, a little way from Tampa that a location for a sanitarium has been recently selected. On the line of the railroad going from Sanford to Tampa are many attractive places in the Pines, Orlando, Winterpark, Longwood, Altamont, and Kissimmee, the latter prettily situated on a lake of the same name. Many find health and comfort on the St. John's River, but it seems to me that malaria must be more prevalent there than in places away from the river.

Anywhere in Florida one is pretty sure to find conditions under which he can lead an out-door life, which answers one of the primary requisites for a health resort. Still the low, and in many portions, swampy character of the soil is a serious objection to its choice as a health resort in many cases.

About twenty miles inland from Charleston, S. C., is a resort much in favor with the Charlestonians, called Summerville. It is far enough away from the coast to escape the frequent east winds, and has a mild, equable temperature. It is in the midst of the pines, and has a pure air and sandy soil. From my experience, however, one must have a good digestion if he would gain any benefit from a sojourn here. There is frequent daily communication with Charleston, and the diversion of a run to the city is an added attraction to the place.

Fortress Munroe or Old Point Comfort does not seem to me to be altogether favorable for a continuous residence, but rather for a limited stay in the spring or autumn. The soil is clayey, the weather uncertain, and fogs are frequent. This opinion is fortified by that of one of the military surgeons whom I met there. The exceedingly attractive and unique life which one finds there, however, and the many excursions by land and water mitigate very decidedly the unfavorable climatic conditions, and succeed in drawing the patient out of doors and out of himself. The peculiar Indian summer days, which are frequent there, are particularly soothing and restful. For those who cannot afford hotel prices, and who desire greater quiet and seclusion than can be obtained at a large hotel, I will give the name of a good boarding house, the only one in fact on the reservation. It is that of Mrs. Eaton's, near the water and opposite the Fort. On the Hampton River, opposite the beautiful grounds of General Armstrong's Normal Institute and the Soldier's Home, is the boarding house of Daniel Cock, of good report, where there are good opportunities for rowing. It is, however, too far away to allow one to enjoy the diversion which the Fort life offers.

To jump from the South to the North, I wish to say a few words in conclusion, upon the Adirondacks, where there are patients not only in summer, but also now quite a colony in winter. Dry it is not, judging from my experience the last summer, and the diurnal variations of temperature are quite great. But despite all this, so far as my observation has extended, consumptives do remarkably well there, provided there are no very acute symptoms. The air is bracing and pure, and the out-door attractions numberless. Everything conduces to keep one in the open air, and persuades to much exercise. The grazing is good, and consequently the milk is abundant and rich. The boarding houses are often poor, but good ones can be found, as all who have made trial of the Mirror Lake House at Lake Placid can testify. I do not know that it makes much difference where one goes in the Adirondacks in the summer; perhaps the portions of about two thousand feet elevation are the best. If one is strong enough, and the digestion is good, camping out probably gives one more pure air than can be obtained in any other way.

Saranac seems to be the winter home for consumptives in the Adirondacks, and has the sanction of Drs.

Loomis and Trudeau. It is better protected from the winds than other places, and commands a good physician. Near by the village of Saranac is the sanitarium recently established — a most admirable charity. It consists of a large main building and several cottages and tents, and, at a small price, one can obtain every needed comfort. The only objection, if it is one, is the bringing together, in such close proximity, a number of consumptives. This did not seem, at least, to have a depressing effect, judging from the cheerful appearance of those I saw there. The sanitarium is kept open all winter, and I have at hand a letter from a lady who has been an inmate of the institution all summer, who wrote me that she has gained so much she proposed to spend the winter there. It was quite noticeable how many began to gain in weight after coming to the Wilderness.

I do not want it understood that I ignore the numerous other health resorts I have not mentioned, or consider those I have the best; I have only spoken of the few I have happened to be personally acquainted with. I doubt not that there are many others far more ideal than any I have mentioned. All know of the remarkable results of the Colorado and New Mexico climatic cure, and of the influence of the climate in certain portions of California, and of the high pine lands of the South, as represented by Aiken; indeed, I think we have in this country a wealth of health resorts from which to choose. I desire, however, to emphasize the fact that there are many other considerations to be carefully weighed in selecting a resort for a consumptive beside the one of the best ideal climate; in fact, that is the best ideal climate for the individual patient which best meets his individual needs, mental and physical, and that in any place where the air is pure, the sunshine constant, and the temperature so adapted to his condition that he can live out of doors, he will improve if improvement is possible.

I will very hastily run over a single case which I think well illustrates the points I have been attempting to make clear in this paper.

In March of last year, I discovered, to my great surprise and alarm, that a member of my family had evidences of consolidation at both apices, accompanied with a moderate rise of temperature. Distrusting my own judgment when thus personally interested, I sought the opinion of Dr. Knight, who very kindly gave it, but corroborated my worst fears. In addition to the pulmonary trouble, the vitality was low, and there was much dyspepsia of many months' standing. The outlook indeed seemed dark, the prognosis grave. Many weeks of trying weather still remained, and I determined that an immediate change of climate was imperative, and that the harsh spring winds must be avoided. The first requisite was such a climate as would enable one to exist with the least exertion, and lead an out-door life. Moreover these conditions must be obtained with as little outlay of strength as possible on the part of the patient. I therefore went with my patient to St. Augustine, reached from Washington in about a day and a night. There I found delightful weather and sunny days, where a delicate person could live out of doors from morning to night, with perfect comfort. Damp no doubt it was and low, far from an ideal climate for a consumptive one might say, but it exactly fulfiled the conditions required for the patient in question, and before the month of April was over, she could walk about the old town, and take a lively interest in what was going on, whereas on her advent, she could hardly get across the street, and was indifferent to surrounding scenes. The lungs remained much in the same condition, to be sure, but the strength was returning, and the drooping spirits had revived.

At the beginning of May, we gradually retraced our steps North, following the strawberries. At Charleston it was the season of roses, and out-door life was delightful. Every day brought an excursion with it. There were also pleasant companions, and so we had again an ideal climate for the especial requirements of this especial case. Loitering along we finally reached Fortress Monroe in its pleasantest season, and here several weeks were spent with benefit to body and mind. Now it seemed to me that the general condition had so much improved that a more bracing climate might with safety and benefit be tried, so our next move was to Lake Placid in the Adirondacks, two thousand feet above the level of the sea. My hopes were realized. From one hundred and three pounds, the weight went up to one hundred and twenty; the dyspepsia almost entirely disappeared, and the consolidation began to clear up. So much had been gained at the end of October that it seemed to me still more might be ventured, and after an interim of two or three weeks, my patient went to Colorado, where she now is, and, I have the most encouraging reports of her well-being and steady improvement.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

THE PELVIS AND SACRUM IN ANTHROPOLOGY.

ALTHOUGH it is unlikely that the skull will ever lose the place of honor as the most important part of the skeleton in comparing races, it is very satisfactory to see other parts of the body brought into requisition. Apart from their probable inferiority to the head in anthropological significance they have the further disadvantage of being comparatively few in number, even in the best collections. None the less it is a great advance to have comparisons made between as many parts as possible. We noticed in these reports a few years ago the researches on the scapular index by the late Professor Broca, in Paris, and by Professor Flower and Dr. Garson in London. The idea of using the pelvis in anthropology is no new one, but in fact we are not aware of any great progress having been made in the last hundred years until comparatively recently.

An evident difficulty in the study was the want of some generally accepted plan of comparing the different parts of the same pelvis, to remove which Dr. Garson proposed in 1881 that the transverse diameter of the brim of the true pelvis should be 100, and that all other measurements should be compared with it. Thus if he were taking the distance between the anterior superior spines of the ilia, the depth of the pelvis or any other measurement, the latter should be multiplied by 100 and divided by the superior transverse diameter of the same pelvis. There are some who would prefer the antero-posterior diameter as the basis, but Professor Turner,[1] by adopting the transverse in his

[1] Journal of Anatomy and Physiology, Vol. xx., October, 1885 and January, 1886.

"Report on the Bones of the Skeleton" in the "Challenger" collection has probably settled the matter. His first paper on the pelvic brim introduces some new terms which, however, are not quite unfamiliar. When the index (obtained by multiplying the antero-posterior diameter by 100 and dividing by the breadth) is above 95 the pelvis is long *dolichopellic*, when below 90 it is wide *platypellic*, and those from 90 to 95 both inclusive are *mesatipellic*. As to the measurements themselves there can be no question that in the case of many races the number of observations is too small to be of much value. Omitting some races which from this cause cannot be placed certainly, we find that Professor Turner gives as *dolichopellic*, Australians, Bushmen, Hottentots, Kaffirs, Malays and Andamans; as *mesatipellic*, Negroes, Tasmanians and New Calendonians; as *platypellic*, Europeans generally, Mongolians generally, and American Indians.

In his second paper he takes up the sacral index but does not compare the measurements to the transverse diameter of the brim of the pelvis, but has chosen to multiply the breadth of the sacrum by 100 and divide by the length. *Hieron* being the Greek equivalent of sacrum we have *dolichohieric* for one in which the length exceeds the breadth and *platyhieric* for one in which the breadth is the greater. Again, omitting races which Professor Turner classes as doubtful from the few observations that were possible, we find the sacral index is above one hundred, that is, that the sacrum is long in Australians, Bushmen, Hottentots, Kaffirs, Andamanese, Tasmanians, and Malays. It is broad in Europeans, Negroes, Melanesians, Hindoos and North and South American Indians. As would naturally be expected, it appears that the broad sacrum is often found in the broad pelvis and the long sacrum in the long one; the latter it is needless to say is the lower form.

THE EFFECT ON THE BLADDER OF DISTENDING THE RECTUM.[3]

Some years ago experiments were made by Braune and Garson and published in German, and a little later published by Garson in the *Edinburgh Medical Journal* of October, 1878, with some facts we believe not included in the former publication. We, therefore, refer to these experiments as Garson's. The rectum was more or less distended, the body frozen and median sections made. It was shown that the effect of distending the rectum was to push the bladder bodily upward, and that the prostatic part of the urethra was stretched and its direction changed. It was also shown that the fold of peritoneum in front of the bladder was carried away from the symphysis pubis. Somewhat later Petersen[4] made observations on the latter point by the method of opening the peritoneum by a cut in the median line, finding the lowest point of the peritoneal fold with his finger and observing its displacement when the rectum and bladder were filled.

The author of the present paper has made a series of similar experiments by means of frozen sections, which are of much interest in many respects. The paper is illustrated by four excellent colored plates. The first section was made to show the position of the parts with an empty rectum and a moderately filled bladder. The latter was filled with 300 ccm.[5] of fluid. The bladder takes up the greater part of the true pelvis. The beginning of the urethra is situated 1 cm. above the level of the lower border of the symphysis and 4 cm. behind it. The fold of the peritoneum leaves the wall of the abdomen only ½ cm. above the symphysis. The recto-vescical fold extends even below the tip of the coccyx.

The next step was to show how a bladder holding about this quantity would be displaced by a full rectum. Unfortunately, however, as it seems to us, the bladder either by accident or design contained only 200 ccm., and the rectum was distended with 480 ccm. The bladder appeared decidedly smaller than in the first plate. It is pushed upward and forward against the front wall of the body and its posterior surface is curved in by the rectum. The beginning of the urethra lies 4 cm. above the lower border of the symphysis and 1 cm. behind that bone. The peritoneum leaves the anterior wall 4 cm. above the pubes. The recto-vesical fold is nearly 5 cm. above the level of the lower border of the symphysis. The bladder is almost crowded out of the pelvis and the prostatic part of the urethra runs nearly straight downward. We have observed this last point in a section of a pelvis in which the rectum was tolerably full and the bladder almost empty.

The next plate shows a section of a body in which the rectum was empty and the bladder much distended, containing 630 ccm. The bladder is nearly round. It fills the true pelvis almost completely. The beginning of the urethra is on a level with the lower border of the symphysis and 4.5 cm. behind it. The peritoneum leaves the anterior wall about 2 cm. above the pubes and the recto-vesical fold comes down as low as the base of the coccyx. The course of the prostatic part of the urethra is very remarkable, it runs almost horizontally forward.

The next and last plate is intended to show the state of affairs when both bladder and rectum are strongly distended. The former was filled with 420 cm. and the latter with 500 cm. of fluid. The picture is a very striking one. We should say, on a rough estimate, that five-sixths of the bladder are above the pelvis. It is somewhat pear shaped, the long axis being vertical. The beginning of the urethra lies hardly 1 cm. behind the symphysis and some 2.5 above its lower border. The peritoneum leaves the abdominal wall 8.5 cm. above the pubes. The recto-vesical pouch is on a level with the top of the symphysis. The prostatic urethra again is nearly vertical. These plates show how movable is the lower part of the bladder and what changes in direction the first part of the urethra may present. They show also that the rectum being empty an over-full bladder tends to occupy the pelvis, at least as much as to expand into the abdomen. A comparison of the first and third plates will make this quite clear. In both the rectum is empty. In the first the bladder is moderately, in the latter excessively full, but we see in the latter that the progress of the bladder downward and backward is very remarkable. A comparison of the third and fourth figures shows further that though distention of the bladder alone carries the peritoneum away from the lower part of the abdominal walls, that this effect is greatly increased by filling the rectum. We infer, both from the silence of the author and from the plates that the bodies were frozen on their backs, and as this is the position in which the patient generally comes under

[3] Dr. Fehleisen. Archiv für Klinische Chirurgie, Bd. xxxii, 1885.
[4] Verhandl. der Deutschen Gesellschaft für Chirurgie, 1880.
[5] 35 ccm. = $\frac{1}{3}$

the surgeon's hands, it is no doubt the proper one; still it would be very interesting from a practical as well as a scientific standpoint to see the results of similar series of experiments in which the bodies should be frozen in both the prone and the upright positions.

STUDIES ON TOPOGRAPHICAL ANATOMY OF THE THORAX.

Dr. Topken[6] has studied the old question of the position of the heart. Although his conclusions present little or nothing that is new, the article is of value owing to the analyses of the works of well-known authors it contains and to the writer's careful observations and experiments. A very useful feature in the paper is a series of diagrams of the front and side of the chest on which the positions of frozen sections are represented. By means of these he discusses the results given in Henke's work on the position of the heart, those in Braune's celebrated atlas and a new series by the same anatomist that have not yet appeared. This paper, therefore, is well worth study. The conclusions condensed are essentially as follows: It is not possible to name a precise spot as the normal position of the apex either during life or after death. In young people the heart is placed higher than in old ones. Generally the heart is found higher after death than in life owing to cadaveric changes that move the diaphragm upward. The heart, however, is found lower after death even in the young, if expiration is impeded at the moment of death as is usually the case in drowning.

Dr. Sick[7] discusses the relations of the pleuræ to the sternum, the position of the valves of the great arteries, which he groups together, and the height to which the diaphragm rises on the right. He examined forty-six bodies of various ages from new-born children to very old age, but the majority of them seem to have been those of persons passed middle life. Our author believes that the diaphragm reaches the level of the insertion of the cartilage of the fifth rib to the sternum. We presume that he means after death. The most interesting question of those treated is the position of the pleuræ in regard to the sternum, and this is of especially practical value as it bears on the operation of tapping the pericardium. It appears that the left pleura is much more likely to reach, or to nearly reach, the left side of the sternum at the fifth and sixth cartilages than is generally supposed. In twenty-three bodies of adults the reflection of the left pleura at the fifth cartilage was seventeen times either behind the sternum or just at its border. At the sixth cartilage in ten cases it was still behind the sternum and in six cases was less than 1 cm. distant from it. At the level of the seventh cartilage in nine cases either the pleura was against the border of the sternum or else its lower reflection had occurred above the point. In two cases it was less than 1 cm. distant at this level. Clearly not very encouraging conditions for the puncture of the pericardium at the left of the sternum if passing through the pleuræ be considered a contra-indication.

As to the position of the arterial valves, out of twenty-seven cases they were found in twelve at the level of the third cartilage, in five at the third intercostal space, and in five at the fourth cartilage. Dr. Sick states that in several cases pins thrust in at the left side of the sternum pierced the aorta.

THE GLAND OF THE NASAL SEPTUM.

Jacobson's organ has of late been held to be present in man in a rudimentary condition. It is described in the ninth edition of Quain, and has been the subject of several papers by Klein in the *Quarterly Journal for Microscopical Science*. It may not be out of place to mention that this organ (in man) is a small canal under the mucous membrane of the nasal septum which opens a little above and anterior to the Stenonian canal. Many glands open into it and a special cartilage lies below it. In the rabbit and guinea pig, in which it is well developed, it receives considerable branches from the olfactory nerve, thus making it appear to be some special sense apparatus connected with smell.

Professor Gegenbauer[8] thinks that the little structure in the human nose above described is not a representative of Jacobson's organ at all, but a rudiment of a nasal gland, which is also found in some mammalia. He bases his view on two points in which the structure in question differs from Jacobson's organ. First, that in man the opening is above the floor of the nasal cavity, and next that the special cartilage lies below it and at some distance, instead of surrounding it as it does Jacobson's organ in all animals that have it.

Hospital Practice and Clinical Memoranda.

A CASE OF CO-EXISTENCE OF SCARLET FEVER AND MEASLES.

BY FRANCIS F. BROWN, M.D., OF READING, MASS.

GERTRUDE F., aged thirteen, was taken Thursday evening, January 28, with an attack of scarlatina anginosa. It was ushered in with vomiting and delirium. The vomiting persisted three or four days, but after the first, seemed to be kept up by the irritation of the fauces, produced by the swelling of the throat. The eruption was out on Saturday, the 30th. The attack was severe, the throat badly swollen, the breath, at first, foul; pulse, 125 to 130; temperature, 103° to 103.9° in the axilla up to the following Thursday.

On Monday, February 1st, there was some cough, and for the two days following, and her face had a peculiar spotty look; this and her next were her sickest days. On Tuesday, her face was covered, mingled with the scarlet fever rash, with an unmistakable eruption of measles; none were seen on the body. Just ten days previously, her younger brother first broke out with the measles. The respiration was hurried also, somewhat, but less so the next day. Wednesday, the eruption of measles had extended over her body and limbs, mingled with the scarlet rash, while on her face, neither could be distinguished; but the skin of it, with the exception of here and there a whitish spot, was of a uniform dark-red color, and elevated, giving it a peculiar look, as if covered with a red mask.

On Thursday, February 4th, the fever had abated, and from this time she convalesced. The general redness and elevated appearance of the face was gone, leaving the eruption of measles again distinct, and it could be faintly seen here up to the 6th and 7th. Both eruptions were fading on the body, and after that day,

[8] Morphologisches Jahrbuch, Bd. XI., 1885.

none of the appearances of measles were seen there, while the redness from the scarlet fever remained a little longer.

This case is reported on account of its infrequency. The case of varicella occurring simultaneously with scarlatina, reported by Dr. Ayer, in the JOURNAL of February 4th, 1886, shows that such distinguished authorities as John Hunter and Hebra were too sweeping in their assertions that the eruptions of two exanthema never co-exist. The appearances in this patient were closely watched and noted at the time, and I do not think I could be mistaken. There has certainly been no lack of opportunity in this vicinity, of studying the characteristic features of measles the present winter.

A little reflection will show that the variety of this combination of the two diseases does not by any means prove their incompatibility. The chances that any patient will be so exposed as to bring on both at the same time are extremely small, and this may in part, at least, account for its infrequent occurrence. A few cases of scarlet fever known to have been fully exposed to measles from ten to fourteen days before, and failing to get it, would tend more to show their incompatibility, than the bare fact of the infrequency of their simultaneous appearance.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M D., SECRETARY.

JANUARY 13, 1886. The meeting was called to order at eight o'clock, by DR. F. I. KNIGHT, chairman.

The first business was the report of a committee appointed in accordance with a motion passed at the last meeting, for the purpose of suggesting some way for meeting the necessary small expenses of the Section. The committee was appointed subsequently to the meeting and consisted of Drs. Henry I. Bowditch, Henry C. Haven and Chas. M. Green. The report of the committee was presented by Dr. C. M. Green, as follows: The committee appointed at the last meeting to devise means of paying the necessary expenses of the Section in Clinical Medicine, etc., beg leave to report, that, although the treasury of the Suffolk District Society bears such expenses as rent, printing and stationery, there are occasionally expenses of such a nature that they must be borne by the Section that incurs them. The committee therefore recommends that an executive committee of three, of which the Secretary shall be one, be appointed to raise, in such way as the Section may see fit, the money to pay such expenses as are not borne by the treasury of the General Society.

DR. GREEN stated that it is desirable that the Section have some funds of its own, from which it may be possible to defray certain small but necessary outlays, such as belongs to the administration of any society. It might also be desirable at times to invite some distinguished member of the profession from abroad, to be present at some of our meetings, and it would seem no more than courteous to be able to remunerate such a guest for the expenses of travel, to say the least. At present the Section has absolutely no funds, and the necessary correspondence of the Secretary is conducted at his personal expense.

DR. H. J. BARNES asked the amount needed by the Section for the purpose stated?

The Secretary replied that during the period of four years, the expenses had gradually increased until the annual outlay now amounted to about twenty-five dollars. This does not include the cost of any entertainment at the close of the meetings, these having been provided on all occasions by the liberality of the members.

DR. GREEN said that the committee did not feel that they were authorized to propose any method for raising the needed sum, from the fact that the members already pay an annual assessment to the Suffolk District Society, and it would seem undesirable that an additional tax should be imposed upon them. It was therefore deemed best to leave the manner of raising the money to the Section.

DR. KNIGHT asked if the treasury of the Suffolk District Society is in a condition to assist the Section?

DR. GREEN, the Secretary of the Suffolk District Society, stated that this is not probable, as the General Society already pays the rent, and the bills for printing for the various Sections. Last year the General Society found it necessary to levy an assessment of one dollar extra, in order to avoid a deficit in its accounts. On motion of Dr. Barnes the report of the committee was accepted, and its recommendations adopted. The chairman then asked for some expression on the part of the Section as to the method to be employed for raising the sum required. The Section was not prepared to adopt any method at this time, and the chairman decided to defer further action until the next meeting.

DR. BARNES moved that the present committee be authorized to collect the amount needed, by voluntary subscription among the members. This was seconded by Dr. E. W. Cushing, and passed unanimously. It was moved by Dr. E. W. Cushing, seconded and passed unanimously that the thanks of the Section are due to the Secretary for temporarily advancing the funds hitherto required, until such time as the section might repay him. The regular business of the section was then taken up.

The first paper was read by DR. E. O. OTIS, entitled,

RANDOM NOTES ON SOME HEALTH RESORTS,[1]

and gave the reader's personal experience in a tolerably large number of places more or less noted as health-resorts during the last winter and spring.

DR. BARNES said that he had been much disappointed in the benefit to be derived from a change of climate to some of the most noted of our resorts. This was illustrated by the description of a trip made by a patient of Dr. Barnes' who was advised to go for the winter to Bermuda for a pulmonary trouble. He sailed from New York in a leaky vessel, stormy weather prevailed during the entire passage, and the patient was frequently drenched with salt water. A few days after arrival the patient was seized with rheumatic fever, and suffered much. He returned after an absence of six weeks, much worse than when he went away, and died a few days after arrival at his home.

As far as climate is concerned, in a health-resort,

[1] See page 221 of the Journal.

there is no doubt of the necessity that the air shall be more or less humid. We keep our houses much too hot, and the air is far too dry for health or comfort to those inhabiting them. A house heated by steam is not comfortable unless the temperature be kept much higher than is necessary in a house warmed by open fires, and particularly if there be ample provision for moisture in the air of the room. The most comfortable room in our modern houses is the kitchen, because there is always a change of air going on from the frequent opening of doors, and the draught of the range. The teakettle is always on the range and furnishes a constant supply of steam, which makes the air moist, as proved by the frost on the windows. Plants will grow in the atmosphere of the kitchen, but they languish in those parts of the house which are supplied with steam heat, or with hot air from a furnace. In moist air, a temperature of 68° is very comfortable, while in air too dry, it is necessary to keep the temperature as high as 75° or 80° in order to feel comfortable.

DR. A. H. NICHOLS stated that a recent hasty visit to the South enabled him to confirm the correctness of the statements contained in Dr. Otis' paper. It is a strange sensation to go in a few hours from a temperature of zero to that of 75°. The defect, however, of most health resorts is that the climate is not equable. This is especially true in the South. The climate of California is better in this respect than that of Florida, and that of Southern Europe is better than that of California. The *ideal* climate is doubtless that of Ovatava in Teneriffe. The coldest weather ever known there compares with our June, while the warmest weather is much like our July with the warmest days left out. A very striking feature of the climate there is the fact that the warmest period of the day is not at noon as we are accustomed to observe in the United States, but at a time before noon. During the middle of the day, a fog-bank rolls in from the sea and covers the land like a huge umbrella, thus effectually protecting the inhabitants from the extreme heat which would otherwise occur. . . . One fact in connection with the southern parts of the United States is quite surprising, that is, that in many places where one would expect to find malaria, the disease is unknown. This is true in particular at some points near the sea, where the air is humid and we find most of the conditions usually met with in malarious localities. The nearness of the sea, with the presence of iodine and possibly ozone, seem, however, to be the agents of protection to these localities from the poison of malaria.

DR. J. AYER remarked that although he had but little knowledge of the peculiar recommendations of the various health resorts, yet it is becoming more and more evident that physicians must inform themselves of the hygienic advantages of the different parts of our country, so as to be able to give an intelligent opinion and suitable advice to those needing a change of climate for any purpose. There are no doubt many places as yet unknown, which possess great advantages as sanitary abodes, and the physician should inform himself in regard to them, as a part of his professional education. In Europe the science of sanitation has reached a degree of perfection as yet unapproached in America. Patients from our own country cross the ocean to obtain the benefit of a change of climate, which our land with its immense area and variety of physical conditions would surely supply.

DR. VINCENT Y. BOWDITCH spoke of the great harm which frequently results from the careless manner in which patients are sent away from home to languish in uncomfortable and crowded boarding-houses, destitute of all the comforts to which they have been accustomed at home, and dependent upon the caprice and interest of hotel-keepers of all kinds, for everything pertaining to their welfare. Then too, one is liable to be misled by the careless statements of those who describe the various places of resort. Thus each locality is vaunted as possessing the "ideal" climate, and other localities are misrepresented. Aiken has been highly recommended by many persons, to the detriment of similar places elsewhere. It is true that this town possesses the advantages of high altitude and pine forests, and the air is doubtless of exceptional purity, but even these qualities are not adapted to all cases. While speaking of remote health resorts, we should not omit to mention those near at hand and which are easily accessible; thus, Wellesley Hills and Sharon are of great service to many cases of pulmonary diseases. The location is high, the air dry, and many of the requisites of a noted resort are attainable at a slight expense of time, strength and money. Patients in both of these places often achieve most gratifying results.

DR. E. L. PARKS stated that he passed the winter of 1877-8 in Santa Barbara, which proved to be a most delightful place of residence. There is no malaria in the town or neighborhood. The extreme between the coldest temperature of winter and the warmest of summer is but forty degrees. These statistics are thoroughly reliable, as they were taken by a gentleman, a physician, who was advised to go there for the benefit of his health, which was fully restored. He remained perfectly well as long as he resided in this place, but he could not live elsewhere, and as a pastime he made a series of careful observations upon the meteorological conditions of the place. The relative humidity is a thing which is a source of the greatest disturbance to many delicate patients. Often a patient who cannot live at the level of the sea, will be perfectly comfortable at an elevation of four hundred feet above the sea.

In a case of this kind the humidity alone is variable, all else remains unchanged. Another thing which is often a cause of disappointment in the effect produced by residence at any health resort is the way in which patients are allowed to make the journey to the new abode. Very frequently a sick person arrives without an attendant; he is not welcome, he may not be able to secure good or comfortable accommodations, and he is entirely at the mercy of those who may be willing to receive him. A case of this kind was known to the speaker, in the person of a gentleman from Boston, now deceased. He came unattended and unknown, he was unable to secure good accommodations, and was not comfortable during his short stay there. Aside from this, he was in a condition quite unsuited to travelling, and should never have been sent from home. A patient may go to Santa Barbara at a certain stage of pulmonary disease and by a prolonged residence, never less than a year, may quite recover. It is, however, worse than useless, to send a patient to Santa Barbara after all the other resorts have been tried. These cases will not be benefitted by the climate of Santa Barbara or that of any other resort. When a patient has reached a certain

stage of the disease, there is no benefit in change to any other climate.

Dr. E. W. Cushing said that the peculiar geological formations at many of the resorts for invalids, such as various parts of California, Nice, Cannes, etc., allows the patient to choose exactly the situation and the surroundings adapted to his comfort. The country rises rapidly from the seashore to the hills, so that an elevation of considerable magnitude may be attained at a short distance from the town, and within a short time from the sea-level. That it is not the "humidity" alone, or even to any great extent, is now generally admitted. The change of scene, the entire rest, the out-of-door life, and the relaxation from all labor are important factors in the amount of benefit to be obtained from a stay at any health resort. One of the most useful adjuncts to all the other measures which may be adopted, is exercise on horseback. Given good food, rest, trees, music and suitable companionship, with the advantages of good society, a sick person will often obtain great benefit from a stay at any proper resort. Throughout the South, however, the boarding arrangements are bad and the accommodations wretched.

Another objection to many, if not most "health" resorts, is the fact that one place after another fills up with phthisical patients, there is often no suitable water supply, and even more frequently no suitable provision for drainage, and the entire place becomes at length charged with the disease, the rate of mortality rises, and the place is ruined as a health resort.

Dr. E. T. Eastman thought that the most important object to be attained is the comfort of the patient. A sick person who is sent to a place where many consumptives are herded together, is quite easily depressed and may die from the moral effect of such melancholy surroundings. No doubt each year many persons die in such places who might recover under more cheerful surroundings. Above all, in the present state of our knowledge of pulmonary diseases, we should avoid the crowding of phthisical patients.

Dr. Knight said that it was gratifying to see that physicians had begun to use some discrimination in recommending climates. The discussion had been mostly restricted to the benefit of change of climate in pulmonary disease, but of course there were many other diseases which might be benefitted by an appropriate change.

A great and beneficial modification of the old custom of sending all cases of pulmonary disease to warm climates has taken place in recent years, a custom which has arisen from giving too much consideration to what might mitigate the concomitant bronchitis. There is no doubt of the great difference in the physical properties of different climates, and no doubt that we can favorably modify pathological conditions by taking judicious advantage of them.

In selecting a climate for consumptives the peculiarities of each patient should be considered, his temperament, the stage of his disease, complications, etc. If permanent arrest of the disease is hoped for, Dr. Knight said that he was always glad if the patient's condition is such as to allow of the selection of a dry mountain climate of considerable elevation. If his peculiarities will not admit of this, then a lower altitude, but still a dry and tonic climate should be chosen. It was unfortunate if a warm, moist climate had, for any reason, to be adopted.

The next paper was by Dr. Herman F. Vickery, entitled,

ENLARGED CERVICAL GLANDS.[2]

Dr. John Homans, 2d, thought that many other causes may exist for enlarged glands besides those mentioned in the paper. Thus rhinitis, pharyngitis, and tonsilitis may cause enlargement of the cervical glands. These are, however, the expression of a general systemic condition and are not dependent upon the local state of the neck.

Dr. Barker mentioned the enlargement of the glands of the neck following surgical operations as illustrating another causation of this condition.

Dr. Vickery said that the enlargement of the glands seems often to be secondary to other conditions. Thus a child pricked the neck with the tine of a fork, to a moderate extent. The prick healed quickly, but soon after there was noticed a distinct enlargement of the glands of the neck which proved to be not adenoma but scrofulous in character.

The next paper was by Dr. Edward B. Lane, entitled

TWO CASES OF CEREBRAL TUMOR, WITH AUTOPSY.[3]

Dr. J. J. Putnam stated that cases of tumor of the brain often present no definite or recognizable group of classical symptoms, by which their location, or size, or frequently their existence even may be determined. Dr. Putnam mentioned a case seen in consultation with Dr. Adams of Watertown, in which almost all the tissue of the pons was replaced by a large vascular glioma.

Dr. P. C. Knapp asked the seat of the tumor?

Dr. Lane stated that it was seated below the basal ganglia, and was evidently pressing upon the crus cerebri.

Dr. Cushing asked if the early recognition of the disease and its treatment by anti-syphilitic measures is of any avail in cases of cerebral syphilis?

Dr. Lane stated that no case is known in which the syphilitic lesion in the brain has been benefitted by any form of treatment.

Dr. Goldsmith has never seen a case of improvement in such cases.

Dr. Putnam remarked that probably that does not mean that no case may be relieved by treatment.

Dr. Lane stated that no case in which the disease was of a sufficient degree of severity to require treatment in an Insane Asylum had ever been known to be benefitted.

Dr. Putnam added that in the early stages of congestion, before deposits of syphilitic growth have taken place, it may be possible to improve the patient's condition. When chronic paralitic dementia has occurred there may well be no improvement from any mode of treatment.

Dr. Knapp added that in cases in which any mental derangement exists there is no hope from any form of treatment.

Adjourned at 10.15 o'clock.

— Pasteur has asked his government for a subsidy of 2,000,000 f. for the establishment of a hospital and for 50,000 f. a year to operate it. It is said that the authorities are in favor of giving him at least the latter grant.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

PHILIP COOMBS KNAPP, M.D., SECRETARY.

JANUARY 21st, 1886, DR. WALTER CHANNING in the Chair.

DR. F. M. TURNBULL read

A REPORT OF THREE CASES OF MELANCHOLIA, BEING ESPECIALLY A CONSIDERATION OF THE PROGNOSIS.

The first case was of a single woman, fifty-one years of age, of good family, with an insane heredity, two aunts and a twin sister being insane. She had always been in good health, except for habitual constipation, and was of a strong intellectual character, and fond of reading. Grief at a nephew's ill-conduct and at her mother's death, and the consequent change in her manner of life, caused her to become depressed. In October, 1882, she conceived the idea that she had acquired syphilis from indulgence in masturbation; she grew very despondent, demanded anti-syphilitic treatment, and finally made several attempts at suicide, which caused her friends to send her to Somerville. On admission, in December, she was extremely depressed, had headache and insomnia, and groaned a great deal; she thought she was contaminated and might communicate her disease. She continued in this way for two or three months; then she began to eat less, and made another attempt at suicide. She had, evidently, hallucinations of hearing, and still held to the delusion that she had syphilis. She gradually grew worse, groaned, and rubbed her hands constantly, slept very little, and was very incoherent in her speech. In June, 1884, she had to be sent to the excited ward; she continued in the same way, rubbed the hair off her head in places, and made several sore spots on her face. In September, she became quieter and talked naturally, but soon grew worse again. In February, 1885, she had the new delusion that her brother had formed some wicked design against her, and she thought she saw him about the grounds. About the same time, she wrote a perfectly intelligible and coherent letter to Dr. Cowles, asking for mercy, and speaking of some of her delusions. After this, she grew worse, groaned constantly, and was very noisy, and at last accounts, was still in a very bad condition, having lost much flesh and strength, and weighing but seventy-three pounds. The morphine treatment was tried, and it occasionally made her stupid, thus quieting her somewhat, but neither that, nor codeine, stimulants, cannabis indica, chloral, bromides, nor bromidia, had any permanent effect.

The second case was a woman of fifty, married, with a good family history. About the beginning of 1884, she became much depressed, and thought that she had lost much property, and that she had committed a great sin and was spiritually lost. She was sent to Danvers, and there, after a period of slight improvement, she became much agitated, lost flesh, and talked of suicide, although she made no attempts at suicide then. She was said not to have false hearing while there. In August, 1884, she was transferred to the McLean Asylum. On admission, she spoke of her delusions, was restless and agitated, and before long made an attempt at suicide. Her agitation increased, she used to walk the floor, moaning and rubbing her head, and often fell or threw herself out of bed, possibly with suicidal intent. She would not converse with the physicians. During this time, she took cannabis indica and bromide. In December, she began to take morphine, beginning with gr. 1-8, and gradually increasing the dose to gr. 9-16, three times a day. Soon after she became less agitated and could be reasoned out of her delusions for a time, although there were still periods when she was restless, agitated and noisy. From this time on, she steadily improved. In August, she was able to go to the cottage at Lynn for the day, and in September, she went away on a visit, enjoying herself very much. In December she was still away, and it was reported that she was much improved and did not want to come back. She was still taking morphine, though in a very small dose.

The third case was not reported. It was a case of melancholia, with delusions of poverty, and of having committed the unpardonable sin, in which treatment was of little benefit but recovery took place after four years' duration.

The importance of prognosis in such cases was then spoken of, and the reader considered the bad heredity and the fact that the delusions were firmly established, as important factors in judging of the prognosis in the first case. Where the prognosis was unfavorable, the morphine treatment did no good; but in the second case, the depression was temporarily arrested by the morphine, and the recuperative forces had time to act.

DR. PAGE said that, as a rule, cases of simple melancholia recovered, but that in cases of delusional melancholia, especially in patients over forty, and in women at about the period of the menopause, if the delusions became fixed, the prognosis was bad. Many of the cases of so-called "nervous exhaustion" sent to the Adams Nervine Asylum were really cases of simple melancholia, and most of them did well on over-feeding, and tonics without bromide. Clouston objected to opium or morphine in the treatment of melancholia.

DR. J. B. AYER spoke of a case of melancholia, coming on at the menopause, and following an attack of pneumonia, which was kept at home all the time. For three years the case seemed hopeless, but she now gets on without a nurse or special treatment at home. She took no morphine worth mentioning. He did not consider bromidia a good preparation for use as a domestic remedy, as each drachm contained gr. xv. of chloral.

DR. TUTTLE said that most of the cases of melancholia seen in hospitals were of the delusional form, but that since the introduction of the system of voluntary admissions, more mild cases were seen at the McLean Asylum. He considered false hearing an important element in the prognosis; where it persisted, the prognosis was usually bad, and the cases rarely got well. He had known of recovery in but three cases of the sort. Opium did good in some cases, but it could not be told whether it would act well in the individual case, except by trial. If a restless case can be quieted with it, it perhaps works well. The second case reported always went backwards on taking off gr. 1-8 from the dose, until the stimulus of going home began to act.

DR. TURNBULL said that there seemed very little that was tangible and available for prognosis in these cases. It seemed almost impossible to say why one case recovered and another did not.

DR. CHANNING thought that mild melancholia did better outside of an asylum than any other form of insanity. He considered false hearing a bad ele-

ment in prognosis. It was common in the simple melancholia seen in prisons. This "prison insanity" was of a depressed type, associated with anæmia and exhaustion; the patients often had delusions of persecution and false hearing. They rarely became excited, but occasionally made an assault. They usually masturbated, did poorly, and gravitated back to prison. The cases were generally chronic, and but a small percentage got well. He had tried codeia in one or two cases without special results. Schüle recommends opium in melancholia, and has had much success with it; Krafft-Ebing also advises it. He considered the acute forms of melancholia, with a good deal of physical disturbance, but without delusions, the most curable.

DR. TUTTLE, in answer to a question by Dr. Page in regard to over-feeding, said that at the McLean Asylum, when a patient would not eat, he was fed. Of late, they had tried giving half a pound of sugar with each meal, which, at least, caused the patient to gain flesh. He thought that codeia had less effect on the stomach and bowels, but that it did not brace a patient up like morphine. He considered the prognosis in mental diseases as mainly a guess, except in general paralysis, and there we could predict only the final result.

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting February 18, 1886.

DR. H. D. CHAPIN read a paper on

RHEUMATISM OF EARLY LIFE.

This, he said, was a subject which, in view of its great importance, had not received sufficient attention on the part of the profession. Although generally very insidious in its advances, it was an affection which was continually crippling children for life. He gave a *résumé* of the opinions of the principal authorities on diseases of children, and remarked that the most of them seemed to think it was not a very common disease in childhood. A few, however, spoke of its great frequency, and this he believed to be the correct view.

He stated that his remarks would be principally based on an analysis of 76 cases which had occurred under his own observation. The number of these at different ages are given as follows:

6 months	1	9 years	9
11 "	1	10 "	10
20 "	1	11 "	8
3 years	1	12 "	7
4 "	2	13 "	9
5 "	4	14 "	4
6 "	6	15 "	2
7 "	3	17 "	2
8 "	11		

During infancy the disease was apparently not very common. In his three cases occurring in infants of six, eleven and twenty months respectively, however, there were well-marked attacks of acute rheumatism, and the diagnosis was rendered the more positive by the fact that in each of the three instances one or both of the parents had also suffered from rheumatism. In regard to heredity he said that it seemed to him an undoubted fact that some state was inherited, which would develop rheumatism under favorable conditions. It was a rheumatic tendency that was inherited rather than the disease itself, as was the case in syphilis. Having referred to the statistics of other writers, he stated that in the great majority of his own cases either one or both of the parents had had rheumatism.

In early life rheumatism attacked more females than males. Of his own cases 50 were girls and 26 boys, and in 69 cases tabulated by Goodhart, 42 were in girls and 37 in boys. As to the part of the body affected, in 43 out of his 76 cases their lower extremities alone were affected, and in 40 of them the knees were involved. In 23 cases both the upper and lower extremities were affected, and in three the upper extremities alone. In two cases the plantar surface of the feet bore the brunt of the attack.

Pain, as a general rule, was not very severe. In children able to express their feelings, stiffness and soreness of the limbs, rather than acute pain, was complained of. There was generally little or no rise of temperature. A decided tendency to repetition was observed, and in one case there were as many as six distinct attacks. A general feature was marked hydræmia, and this was to be regarded an important factor both as regards diagnosis and treatment.

The absorbing interest in rheumatism in early life, however, centered about the heart. In 26 out of his 76 cases, or one-third of the whole number, there was organic valvular disease, and in 18 of this number there was a mitral regurgitant murmur. Of Goodhart's 69 cases, 15 had organic disease of the heart, and five other pronounced symptoms of organic disturbance. It was worthy of remark that endocarditis was by no means so serious in children as in adults, and therefore it might entirely escape attention. It appeared to him, he said, that the heart became affected only after several attacks of rheumatism; and hence it could be seen how very important it was to make an early diagnosis of the latter disease, and place the patient under appropriate treatment in order to ward off subsequent attacks, with increased danger of cardiac complication. The proportion of cases in which the heart became involved, as compared with the number in adults, had not as yet been definitely determined.

Chorea, as was now generally recognized, had a direct connection with rheumatism. In 38 cases of chorea which he had tabulated in a paper read before the New York Neurological Society in 1883, Dr. Chapin found that 22 had been preceded or were accompanied with rheumatism; and he thought it possible that the two affections, as well as the heart trouble so frequently met with in each, are due to a common cause. In many of his cases chorea did not appear until after several attacks of rheumatism. He had met with 15 cases in which acute tonsillitis appeared before, during, or after attacks of rheumatism. This association of the two affections could not be proven to be anything more than a coincidence; but it was so frequent as to have attracted the attention of a number of observers.

The diagnosis of rheumatism generally depended on the considerable number of corroborative symptoms, rather than the marked severity of one or two. As to the pathology of the disease the lactic acid theory was probably correct. There were in the system both the lactic acid resulting from fermentation in connection with faulty digestion and sarco-lactic acid, which was developed in the muscles.

In speaking of the treatment, Dr. Chapin said that it was highly important when it was hereditary to check the rheumatic tendency at the outset if possible, and to this end all appropriate hygienic and preventive measures should be adopted. In an attack of

rheumatism he was accustomed to commence the treatment with a dose of Rochelle salt, and follow it up with oil of winter-green and salicylate of sodium. If any disturbance of the heart was shown, he insisted on the most absolute repose in the recumbent position. When endocarditis or pericarditis was present, bodily exercise might be of the greatest possible mischief, as irreparable damage to the heart might ensue if prolonged rest was not secured. Rest enforced for several months he believed sometimes had a curative effect and prevented permanent injury of the organ. The long-continued use of such agents as iron and cod-liver oil was also to be resorted to.

DISCUSSION.

In the discussion which followed, which was under the auspices of the Section on Obstetrics and Diseases of Women and Children, Dr. J. LEWIS SMITH read a short paper, in which he said that he had notes of 73 cases of rheumatism in children. Whether there was or was not a *materies morbi*, such as lactic acid, in this affection, he had observed two principal exciting causes, namely: taking cold and scarlet fever. Inherited predisposition was also common. The disease was rare under the age of two years, but occasionally occurred. In most cases in children the symptoms were much less severe than in adults. It usually began in the lower extremities and thence extended upwards; but the reverse of this was true in scarlatinal rheumatism, where the trouble, as a rule, began in the upper extremities.

But however mild the attack might be, rheumatism was a dangerous malady in children on account of the liability to heart-trouble which characterizes it. Endocarditis might begin as early as the second or third day, and in one instance he had observed it on the very first day of the attack. If the child escaped this complication for the first week and proper remedies were kept up, the chances are that endocarditis would not occur at all. In 43 out of his 73 cases there was a mitral regurgitant murmur, and one case of embolism had been noted by him as a result of endocarditis. Pericarditis was much more rare than endocarditis, although there was little doubt that it was more frequently overlooked than the latter.

As to the association of chorea with rheumatism, out of 68 cases of chorea which he had noted, 26 of the patients had had rheumatism one or more times. Usually the rheumatism preceded, but occasionally the chorea set in as early as the latter. Of the other 42 cases of chorea, in 11 one or both parents, and in one other a sister, had had rheumatism. Therefore, in about 50 per cent. of his cases rheumatism was noted either in the patients themselves or in near relations. Dr. Smith said that he should like to emphasize what had been said in regard to the importance of making an early diagnosis, and placing the patient as soon as possible under appropriate treatment.

The best remedy he thought was salicylate of sodium. If given sufficiently early and in large enough doses, he believed that it would in a large number of instances prevent cardiac complications. He would recommend that it should be commenced on the first day, if possible, and given in doses of ten to fifteen grains to a child four or five years old. Given under these circumstances he had come to regard it as a specific. In cases, however, in which the disease had already continued for some time, its good effects were much less apparent. As to the origin of the lactic acid, provided this was the essential cause of rheumatism, he thought that Dr. Chapin was probably mistaken in attributing its formation to fermentation in the process of digestion, for the reason that in infants in whom the lactic acid fermentation was by far the most abundant, rheumatism was much more rare than in older children.

DR. MALCOLM MCLEAN said that he was inclined to believe that if the minute history could always be ascertained, it would be found that heredity was a factor in every single case of rheumatism. As to the so-called "growing-pains," he believed that they were invariably due to rheumatism, and that the physician should on this account not underrate their importance. In some cases of chorea he had observed an accelerated condition of the heart's action remaining, sometimes for years, after the choreic trouble had disappeared; although no cardiac disease could be detected by the most careful examination. This seemed to show an undoubted rheumatic element.

DR. L. EMMETT HOLT remarked that this typical rheumatism was very rare in children: but if pains were taken to discover it, it would be found that rheumatic disease was nevertheless very frequent in this class of subjects. In these indefinite cases it was necessary to seek out the attendant conditions, and inquire into the matter of heredity. There was a marked tendency among the later writers to trace a strong connection between quinsy and rheumatism. As to the ordinary follicular tonsillitis, however, he doubted whether there was any special connection between the two, as in 200 cases of the latter he had not been able to find any apparent association with rheumatism.

The President, DR. A. JACOBI said that heart-disease was very frequent in children, and this was due to two causes, *first*, sepsis, which was rare, and *second*, rheumatism, which was the cause in the vast majority of instances. The cases of congenital cardiac disease were those of the right side of the heart, and these usually terminated fatally at so early a period of life that it was not necessary to take them into consideration. As a rule, the younger the child was, the less prominent the joint affection in attacks of rheumatism. As to so-called "growing-pains," he thought a word of caution was necessary. Dr. McLean had remarked that the diagnosis of growing-pains ought never to be made, and when the parents mentioned that a child was suffering from such pains it should always be treated for rheumatism. It was no doubt true that such pains were very frequently of rheumatic origin; but they might be due to two other causes also. In the first place the affection might be a neurosis, and there was sometimes œdematous swelling about, but not in, the joint. Secondly, there was such a thing as *real* growing-pains. When the epiphyses and cartilages were developing rapidly, hyperæmia always resulted, and this might be so marked as to cause the pain complained of.

DR. J. LEWIS SMITH said in reference to the acceleration of the heart's action without appreciable cardiac lesion mentioned by Dr. John McLean, that he called to mind a case of this kind in which the autopsy showed the presence of well-marked endocarditis. Yet during life there had been no murmur whatever. He had presented the specimen to the Pathological Society, and the examination of the heart was made with great care by Dr. Francis Delafield. Endocardi-

tis was not necessarily accompanied by such lesions of the valves as to give rise to murmurs.

Dr. Chapin said that he wished those present would endeavor to assist him in collecting cases in which there had been evident valvular trouble which afterwards entirely disappeared.

Dr. Jacobi remarked that there were a certain number of cases in which a cardiac murmur disappeared after lasting perhaps only a day or two, or perhaps for a longer period. There were probably instances of simply a rheumatic murmur, and not really of endocarditis. What was taken for endocarditis was in fact rheumatism of the heart muscle. But in other cases there was true endocarditis, attended with a murmur, which after a longer or shorter period entirely, or almost entirely, disappeared. A heart in which this took place was not strictly a normal one, being larger than it should be; but compensation was so ample that no murmur resulted. This change usually took place a little after the age of puberty, and it was more liable to occur in males than females. Dr. Jacobi said he knew of several cases of this kind in the city, where the patients were now grown men, and entirely free from any appreciable cardiac trouble. Dr. Smith had called attention to the fact that endocarditis might occur without valvular disease. This was, no doubt, true; but in the larger number of cases of endocarditis without a murmur, the disease was probably of ulcerative character. In the ulcerative form of endocarditis the valves were affected, but the difficulty was not on top of the valves but at their insertion.

Recent Literature.

Hunterian Lectures on some of the Injuries and Diseases of the Neck and Head, the Genito-Urinary Organs, and the Rectum. Delivered before the Royal College of Surgeons of England, June, 1885. By Edward Lund, F.R.C.S., Member of the College and Court of Examiners of the College, Consulting Surgeon to the Manchester Royal Infirmary, Professor of Surgery in the Owens College. London: J. & A. Churchill. 1886.

These three lectures, on the subjects indicated by the title, give the result of the author's experience during a long surgical practice. They are eminently practical, dealing only with such cases as have fallen to the lecturer for treatment and giving the success and failure which he met with. They have all the charm that belongs to autobiographical writing. No surgeon can read the lectures without being entertained as well as instructed; and we feel sure that few Americans can read the little book without wishing that lectures of the same kind that should induce men to lay before their brethren the experience of their lives, were more numerous in this country.

— We observe by the daily press, that a Newark doctor who has kept watch over some dogs bitten by one of the same rabid creatures that snapped at the children who were sent to Paris to be treated by Pasteur, is prepared to swear that the cur was not mad at all. His bitten dogs have grown fat, and have thus far shown no signs of rabies.

Medical and Surgical Journal.

THURSDAY, MARCH 11, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by Cupples, Upham & Co., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 Washington Street, Boston, Mass.

ARSENICAL WALL-PAPERS.

Our readers will notice from an article in another column that an order has been introduced in the Massachusetts Legislature which, in substance, directs the committee on public health to consider whether or not any legislation is necessary relative to the presence of injurious substances in wall-paper. Attempts have heretofore been made in this State to secure legislation prohibiting the manufacture and sale of papers containing arsenic. Determined and well-organized opposition on the part of the manufacturers and dealers has rendered all such attempts unsuccessful; but the repeated agitation of the subject, not only in this country but in Europe, has added much to our knowledge regarding the extent of the use of arsenical pigments at the present time in the manufacture of wall-papers and regarding the deleterious effects which result from such use.

The matter is one of great importance in its relations to the public health and has received the careful consideration of competent scientific authorities. It seems proper at this time therefore, to state briefly such facts in regard to the subject as, in our opinion, are established by competent evidence, and to consider if the opposition to legislation rests upon any substantial foundation.

The demand for legislation is based essentially upon two considerations: (1) that arsenical pigments are used very extensively at the present time in the manufacture of wall-papers; (2) that arsenic, when thus used, is very deleterious to the public health, giving rise frequently to disagreeable and sometimes to dangerous symptoms.

It is not denied, we believe, that arsenical pigments have been used in times past in the manufacture of wall-papers; but one of the main arguments made use of by the manufacturers, in their opposition to legislation, is that no arsenic is used at the present time. It is without doubt true that compounds of arsenic, such as Scheele's and Schweinfurt green are not much used nowadays in the manufacture of paper-hangings. The dangerous character of these pigments is now so well

recognized that they have been largely replaced by other pigments. It is a fact, however, easily demonstrated by chemical analysis that a large number of the pigments used in the manufacture of paper contain arsenic, either because arsenic has been used in the manufacture of the pigment, and not removed subsequently, as is sometimes the case with the aniline colors, or because some compound of arsenic has been purposely added to the color by the color manufacturer.

It is probable that most of the manufacturers are ignorant of the exact chemical composition of the pigments used by them. They may, therefore, not be aware of the fact that many of their pigments contain arsenic: and it is reasonable to suppose that some of those who guarantee their papers free from arsenic, do so in good faith simply on the strength of their belief that they are using non-arsenical colors. It is obvious however, that any guarantee of this kind is worthless. If it is not based upon a trustworthy analysis of the paper or of the materials used in its manufacture, it does not afford the public the protection which it asks. That arsenical pigments are extensively used in the manufacture of wall-papers is evident from the experience of chemists in Boston alone, which shows that about twenty-five per cent. of the samples submitted for analysis are arsenical. Among the arsenical papers it is not unusual to find some which are guaranteed, by the manufacturer, free from arsenic. Reference to an article by Dr. E. S. Wood, published in the public health supplement to the Fifth Report of the State Board of Health, Lunacy and Charity of Massachusetts shows that the amount of arsenic in these papers may be as high as six to seven grains per square yard, and that one color is as liable to be arsenical as another.

A favorite argument of the opponents of legislation on this subject is that the presence of arsenic, assuming it to be present, is accidental and unavoidable; that it is derived from the size used in the manufacture of the paper. This is, however, an unimportant source. That traces of arsenic may occasionally be explained in this way is very likely true. Analysis, however, shows that the arsenic exists in the color in most cases. Moreover, the amount of arsenic is, as a rule, entirely inconsistent with the theory that it is derived from the size. Assuming, however, that it is a constituent of the size, it is just as dangerous as though it existed in the pigments.

The evidence regarding the deleterious effects of arsenical wall-papers is very conclusive to an unprejudiced mind. A very large number of well-authenticated cases of wall-paper poisoning are recorded. Many of these are readily accessible for reference, since they have been incorporated into Dr. Wood's article; but besides these, numerous cases are to be found in the medical journals. An analysis of the symptoms in these cases show that the arsenic acts upon the system both locally and constitutionally. The first symptoms are the result of the local action of the arsenic, and consist of irritation of the mucous membranes of the eyes, nose and throat, dry cough, loss of appetite, nausea, a feeling of uneasiness in the stomach and intestines, and sometimes vomiting and diarrhœa. Among the latter symptoms produced by the constitutional action of the poison are headache, sleeplessness, muscular debility, depression of spirits, attacks of dizziness and neuralgic pains in various parts of the body. These symptoms are undoubtedly due in many cases to the inhalation of minute particles of arsenical dust. Repeated analysis of the dust which has collected in rooms papered with arsenical papers show conclusively that such arsenical dust is continually detached from the paper. It is proven, however, that under certain conditions, a portion of the arsenic in wall-papers is given off in the form of arseniuretted hydrogen; and it is the opinion of competent authorities that the symptoms, in many cases are due in part, at any rate, to the inhalation of this exceedingly poisonous gas. All the symptoms described will not be observed in every case since they are subject to many variations, depending especially upon the length of exposure and upon idiosyncrasy.

It has been argued that, as the number of persons exposed who experience symptoms of poisoning is comparatively small, there is no necessity for legislation. This is, in our opinion, an unimportant objection. In many cases the symptoms have undoubtedly been attributed to other causes, inasmuch as the catarrhal symptoms resemble those of an ordinary cold, while the gastro-intestinal irritation, if comparatively mild, may readily be attributed to indigestion. There is good reason, therefore, for believing that the number of cases which occur is in excess of those which are reported.

The positive evidence which we have at the present time leaves no room for doubt in unprejudiced minds that some legislation on this subject is necessary. The question has been strongly agitated in Europe and the strict regulations which exist in some of the European countries show that the present agitation in Massachusetts is not a merely local affair. In Germany the sale of arsenical paper-hangings is punished by a fine of one hundred and fifty marks; and, if we understand the law correctly, the seller of an arsenical paper is, in addition, liable to imprisonment upon proof that any injury to health has resulted from such arsenical paper. The Swedish law is exceedingly stringent prohibiting the sale of wall papers containing more than one four-thousandth (approximately) of a grain of arsenic in sixteen square inches. In both Baden and Bavaria the use of arsenical colors in the manufacture of wall papers is prohibited.

We cannot see that legislation will in any way prove detrimental to the manufacturers. It is conceded that arsenical pigments are not essential in the manufacture of wall papers, and that non-arsenical pigments of any color can be obtained of satisfactory brilliancy and durability. We do not consider it necessary that the prohibition of arsenic should extend to minute traces, which are frequently unavoidable on account of the

wide diffusion of small quantities of arsenic. A committee of the National Health Society of Great Britain, in a report presented to the Society in 1883, concluded as a result of their investigations, that an allowance of 0.001 grain per sample of sixteen square inches would be ample for accidental and unavoidable contamination; and that this quantity would not be injurious to health. The manufacture of papers which shall come within this limit is practicable and can be reasonably demanded. In fact a large proportion of the wall paper made at the present time comes within this limit. Certain of the English manufacturers take great pains to exclude all arsenical colors; and they are so successful that it is only rarely that one of their papers is found which contains more than the merest trace of arsenic.

It is highly important that the method of analysis to be employed in testing papers should be clearly defined. It is a matter of frequent occurrence that papers which are guaranteed, by the dealers free from arsenic, are found to be highly arsenical. A failure to detect arsenic in an arsenical paper is presumably due to the employment of inaccurate methods of analysis. It is, we think, very evident that a law which prohibits the manufacture and sale of arsenical papers, but at the same time allows the chemist to employ a method of analysis which fails to detect arsenic in a paper containing three to five grains per square yard, will afford the public but little more protection than it has at present.

THE CAUSATION OF PLEURISY.

Germain Sée in his most recent work on "Simple Diseases of the Lungs," arranges the numerous varieties of pleurisy into two great categories: (1) Pleurisies by propagation; (2) Pleurisies by infection. The group of pleurisies from cold (pleurisy *à frigore*, or idiopathic pleurisy) he divides up, apportioning a part to the first category and a part to the second. He denies that cold is, properly speaking, a *cause* of pleurisy, and thinks that it can only favor the development of pleural inflammation by permitting the real cause to act more rapidly or more efficaciously.

Pleurisies by propagation take their origin from lesions of the thoracic walls, thoracic organs or neighboring viscera. Among the parietal lesions are osteoperiostitis, costal caries, parietal phlegmon and even cancer of the mamma. Other propagating lesions are broncho-pulmonary inflammations (pleurisy is a constant accompaniment of acute fibrinous pneumonia); pericarditis (especially when the latter is due to rheumatism); hepatic affections, such as acute hepatitis, hydatic cysts of the convex surface of the liver, atrophic or hypertrophic cirrhosis: here the pleurisy is generally right sided and the propagation takes place by the lymphatics.

Among the pleurisies by infection, first in the order of importance and frequency is tuberculous pleurisy. Tuberculosis is a very common etiological condition of pleurisy, being the determining cause in three-fourths of the cases, according to Professor Sée. Fiedler's statistics in this regard are very instructive; out of 112 cases of pleurisy treated by thoracentesis, only 21 recovered — of the 91 other patients, 25 died of phthisis at the hospital or at their homes, 66 got well of their pleurisy but were found to be victims of confirmed phthisis or other tuberculous affections.[1] Pleurisy has also been known to supervene in the course of diseases unquestionably rheumatic, and hence in these cases might properly be ascribed to the rheumatic virus, which Sée considers of an infectious (microbiotic) nature. Lastly, all the infectious diseases properly so called — scarlet fever, measles, surgical or puerperal pyæmia, typhoid fever, small-pox, blennorrhagia, etc., may be attended with pleurisy as a part of their manifestations.

As for the pleurisy which so often accompanies chronic Bright's disease, two explanations may be given. Either the pleurisy is the result of the pulmonary lesions which are so frequently a concomitant with Bright's disease, or else it developes in consequence of the general hæmic alterations of that disease which provoke pleurisy as they do inflammations of other serous membranes. If the latter explanation be the correct one the pleural inflammation would belong to Sée's second category.

The views of the French professor will not probably be generally accepted, as there doubtless do occur cases of simple acute pleurisy which are more easily referred for their origin to exposure to cold than to any other cause. Yet it is quite possible that such cases are fewer than one would suppose, and that pleurisy in this respect resembles peritonitis which is rarely idiopathic, and rarely *à frigore*.

MEDICAL NOTES.

BOSTON.

— Dr. H. J. Bigelow has declined to accept the appointment which was tendered him at the Massachusetts General Hospital as "surgeon emeritus," and also the five beds which were placed at his disposal.

— Dr. David Hunt gave an interesting talk before the members of the Boston Medical Library Association last Friday evening, on the subject of engravings in relation to medical men and medical science. The speaker illustrated his remarks freely by an exhibition of a wide range of engravings on professional subjects and of doctors of varying degrees of note and notoriety.

— In the third annual report of the West End Nursery and Infants' Hospital recently presented, the directors, on behalf of the corporation, express their most grateful acknowledgment of the kindness and liberality of those whose aid has enabled them to carry on the work of the institution during so much of the past year. Although obliged to close the Nursery four

[1] Cited by Sée.

months on account of lack of means, during the remaining seven of the eleven months included in this report, one hundred and sixteen infants and thirty-three mothers have been cared for. The objects of the institution are these: 1. The cure of disease, or alleviation of suffering in children under two years of age. 2. The prevention of suffering and disease by securing proper care to infants. 3. The teaching to mothers the proper care of infants, especially in regard to the proper methods of artificial feeding. The directors make, in behalf of the enterprise, the following appeal:

We are especially anxious to secure annual subscriptions. However little sum you may be inclined to give, will you not help that little? If we can secure the necessary amount for the annual expenses from donations, we can hope from other sources, which have aided us in the past, to pay the mortgage on the building now owned by us, and in the future, possibly secure a new and properly-arranged building. The annual cost of the maintenance of a free bed for mother and child is $250; an annual donation of this amount makes the giver a member of the corporation, and entitles him to have the bed occupied by any suitable case he may recommend. An early reply to this appeal is solicited, in order that the directors may decide on the possibility of the continuance of the work of the institution.

Subscriptions may be sent to Dr. H. C. Haven, No. 19 Exeter Street; or to William Minot, Jr., No. 39 Court Square.

NEW YORK.

— The Commencement exercises of the American Veterinary College were held at Chickering Hall, March 1st, when diplomas were conferred on twenty-eight graduates.

— The forty-fifth annual Commencement of the Medical Department of the University of the City of New York was held at the Academy of Music, March 6th, the graduates numbering one hundred and seventy-three.

— The sum of $4,160 has been received at Newport for the payment of bequests made in the will of the late Charles Henry Russell, of New York. Of this amount, $2,080 goes to the Home for Friendless Children, and $1,080 to the Newport Hospital.

— Dr. Gaspar Griswold, Demonstrator of Anatomy in Bellevue Hospital Medical College, and one of the most accomplished and best known of the younger physicians of New York, died of acute peritonitis, after a five days' illness, on the 4th of March. He was born in the city April 24, 1856. He was the only son of the late James Clinton Griswold, and was graduated from Columbia College in 1876. While in College, he distinguished himself in athletics, as well as in scholarship, and was a member of the famous crew which won the intercollegiate regatta at Saratoga in 1874. After completing his medical studies (graduating from Bellevue Hospital Medical College, in 1878), he became an interne of Bellevue Hospital, passing the best competitive examination of the year. When he had completed his term of service at the hospital, where he showed himself a physician of more than ordinary accomplishments and ability, he continued his medical studies in London, and became a member of the Royal College of Physicians. After his return to New York, he was taken into partnership by Dr. Fordyce Barker, and since then, has been actively engaged in successful practice. He was a Fellow of the New York State Medical Association and New York Academy of Medicine, and a member of the New York County Medical Association, the New York County Medical Society, and the Clinical Society; and his funeral, which was held at Zion Church March 6th, was largely attended by his professional and other friends.

— The State Board of Health met on March 3d, at the Murray Hill Hotel, when Dr. Louis Balch, who has been for some time Secretary of the Albany Board of Health, was chosen Secretary, in the place of Dr. Alfred L. Carroll, resigned. Dr. T. C. Curtis, the Acting Secretary, reported the work done at the Central Office since the last meeting, and gave an account of the efforts made to ascertain the cause of the recent epidemic of typhus fever in the Albany Penitentiary. The origin, he said, had not been successfully traced, but the outbreak was now entirely suppressed. It is supposed that the first case was imported from New York, as that was the only place in the State where the disease existed at the time. The results of vaccination throughout the State, to ward off the threatened invasion of small-pox from Canada, were, the Secretary reported, extremely gratifying, and in this connection, he said: "Two facts have been demonstrated: first, that vaccination is a certain preventive of small-pox; and second, that the virus furnished by the New York Board of Health is most efficacious."

Mr. James T. Gardiner, the consulting engineer of the Board, made an elaborate report on the bad sanitary condition of the new Capitol at Albany. At the last meeting of the Board, Dr. Millbank, of the State Insurance Department, reported that he had been attending a number of cases in that department, which he believed to be due to filth poisoning, and it was in consequence of this, that Mr. Gardiner made a thorough examination of the entire building. He found it in a deplorable condition, both as regards ventilation and drainage, the air-shafts, for instance, being placed so near the soil-pipes on the roof, that the strong suction down the former draws down the foul gas escaping from the latter, and distributes it throughout the entire building, while the drainage-pipes in the basement are wholly inadequate. An appropriation for remedying the defects will be asked for at once.

The Executive Committee presented a report on beer, which contains the tabulated results of the examination of nearly five hundred samples, purchased in open market throughout the State, which was made at the request of the Board, by Prof. F. E. Englehardt, of Syracuse. The report points out that there is no legal definition of what constitutes normal beer, nor any standard established by the authorities on the subject, and makes the following recommendations:

That the law be amended so as to define the normal condition of malt beverages. That a malt beverage should, as its name indicates, contain only malt, hops, water, and yeast, and their constituents. That Con-

gress should pass a law making it obligatory upon the Internal Revenue Department at all times, to permit publicity to be given to the ingredients reported by the brewers and dealers of malt beverages. That local Boards of Health throughout the State should have special control over breweries within their jurisdiction; should visit them, and report publicly upon the condition of these establishments. That nothing but pure water should be allowed in the brewing of malt beverages. That local Health Boards of the State should have special supervision over saloons; should have samples purchased of the beverages sold, and forward the same for examination, and that arrangements should be made that the expense of such analyses should be defrayed by the Board of Excise. That no condition of secrecy should be imposed in the law relating to beer, spirituous, or malt liquors, and that it should be admissible, in case any sample be found impure, to make the matter public.

CHICAGO.

— The forty-third annual commencement exercises of Rush College took place at Central Music Hall on the 16th ult. The graduates in a regular course numbered 156; the Honorary degree was conferred on five gentlemen: Dr. Daniel Hack Tuke, of England; Dr. Grant, of Cairo, Egypt; Dr. Haeker, of Hamburg, Germany; and Drs. Hanna and Sheffield, of Illinois.

The annual dinner given by the Faculty to the Alumni occurred in the evening, over four hundred of the Alumni being present. The attendance of students at this school the past term was something over four hundred.

— A few months ago, the organization of a Polyclinic was announced, independent of any other medical school. Now there has been formed another school of this class, to be known as the *Post-Graduate Medical School of Chicago.* It appears to have been created to take the place of the Practitioners' Course of Rush College, and it combines the clinical teaching of the College, the Central Free Dispensary, the Presbyterian Hospital, the Eye and Ear Infirmary, and to a degree, the County Hospital, in addition to the laboratory work of the College. No announcement has yet been issued, but the school will probably be in session during June, July, and August of each year. The fate of this school remains to be seen, but it has the good fortune to be able to start upon what it has, and without the building up of any clinic, or dispensary, or hospital, or the expenditure of money for buildings, and apparatus and furniture. If it does not succeed, it will not be owing to a lack of facilities and material for teaching.

— The *Chicago Hospital for Women and Children,* which has, since the great fire, occupied a moderate-sized dwelling-house on the corner of Ogden Avenue and Adams Street, has just moved into its new and commodious building situated on the same ground. The new hospital will increase the capacity of the institution many fold. It is a substantial, plain, brick structure; is provided with many modern devices for rendering hospitals free from danger to the sick, including the construction of the laundry and mortuary in a separate building, which also has isolation wards for infectious cases, and is, altogether, a credit to the friends of the institution and to the city. The hospital was founded nearly twenty years ago by Dr. Mary H. Thompson, who has always been its chief surgeon, and it has never had a regular attending physician or surgeon who was not a woman. It has a consulting staff of masculine doctors, but from the first, the design was to furnish an opportunity to women physicians to practise the art, as well as to care for sick women and children, and this purpose has never been deviated from. Dr. Sarah Hackett Stevenson is the attending physician.

Miscellany.

RECENT LEGISLATION IN MASSACHUSETTS ON SUBJECTS OF PUBLIC HEALTH..

LEGISLATIVE Committee hearings were continued last week upon the subject of water gas, in which Health Officer Abbott and Professor Sedgwick repeated the evidence already published in the Health Supplement of the Annual Report of the State Board of Health, Lunacy and Charity.

The Committee on Public Health also continued the hearings upon the petition for legislation to forbid the manufacture and sale of wall-papers containing poisonous substances. On Tuesday March 2, testimony was given by Professors D. G. Lyon, Henry B. Hill, Charles R. Sanger and Walcott Gibbs, besides persons who had had personal experience of poisoning from arsenical papers, and numerous letters were read in support of the petition.

On Thursday last further testimony to the same effect was offered. Professor Lyon read a letter from Professor Kinnicutt of the Worcester County Free Institute of Industrial Science, in which the latter says that of 126 wall-papers examined by him twenty-six contained more arsenic than is allowed by English chemists, fifty contained arsenic in smaller quantities, and only fifty were free from it.

Dr. Edward S. Wood of Harvard Medical College, the author of "Arsenic as a Domestic Poison," in a recent State Board of Health Report, said that since this paper was published evidence had increased largely. The contact of arsenical compounds attacked the mucous membrane of the eye, throat, mouth and stomach, after which the nervous system was undermined, the results being shown in nervous headache and all sorts of neuralgia. All these symptoms ceased or decreased when the sufferer left the house containing the arsenical paper. His investigations had convinced him that the use of arsenic is not necessary in the manufacture of wall-papers, and it did not seem that a law limiting the amount of arsenic to one-half grain per seven square yards, as under the English law, would be unjust to the manufacturers. This quantity of arsenic could be detected by the Berzelius-Marsh test. He had never found, except in one instance,

traces of poison in carpets. Senator Harlow here suggested that the petitioners might have the scope of their petition extended to include fabrics other than wall-papers. On cross-examination Professor Wood said he had found arsenic in calico and in cretonnes, but none in silks. In his opinion it is not essential to employ arsenic in the manufacture of any of these fabrics. If a law were passed defining the limit of arsenic permitted, the form of that test should be stated. Arsenic is sometimes put into paste to prevent its souring.

A draft of a bill was submitted by Professor Sanger, prohibiting the manufacture and sale of wall-papers containing more than one-fourth of a grain of arsenic to the square yard, and permitting the sale of such papers containing not more than one-fourth grain to the square yard. Mr. Bailey also submitted a bill prohibiting more than 1-100 of a grain to the square foot, under penalty of not less than $50 for the first offence and $100 for subsequent offences. The remonstrants will be heard on Friday, 12th.

The Public Health Association also gave a second hearing on the subject of the amendment of the existing laws as to the inspection and sale of milk. Milkmen were heard as to the injustice of the present standard of 13 per cent. solids, claiming that with some cows and at certain seasons, even pure milk did not reach that standard. One contractor stated that he agreed to furnish the City Hospital with milk having 13½ per cent. solids, but it is under verbal understanding that the percentage was higher than could be reached, and that the firm shall only be required to give pure milk.

The bill to prohibit the selling or giving of tobacco to persons under the age of 16 years, which passed the House a few days ago, was passed to be engrossed by the Senate, the vote standing 18 to 14.

Correspondence.

LETTER FROM VIENNA.

HYPNOTISM IN LABOR.— CORROSIVE SUBLIMATE POISONING.

VIENNA, February 23d, 1886.

MR. EDITOR,— In your issue of January 21st, an account is given of a case of labor under hypnotism. While the details of the case are correctly given, the honor of employing these means, should, in my estimation, be given to an American, Dr. Chas. S. Sargent, of Boston, at the present time pursuing his studies here.

Having visited Paris previous to coming to Vienna, Dr. Sargent had the opportunity of studying hypnotism and its effects under Professor Charcot. It seemed to him that these means might be applicable in lessening the pains in childbirth, and while working in the wards of Professor C. Braun, he asked permission of Dr. E. Pritzl to experiment upon a patient, which being given, the experiment was performed with success.

Permission was also given to hypnotise when this patient was in labor, but at the time Dr. Pritzl performed the experiment with the result as stated. The two other cases reported were not delivered under hypnotism but were only experimented upon with indifferent success.

As too much care cannot be exercised in the use of corrosive sublimate, and too much attention cannot be given to the administration of intra-uterine injections, the following notes of a case in Carl Braun's Clinic may not be amiss.

Frau F., twenty-three years old, second child, presented herself at the hospital, being in labor. Temperature 38.3°C Central vaginal examination showed transverse position, head on the left, back to the front, with cord pulseless; version was performed with extraction. As there was a suspicion that the rise in temperature might be due to some intra-uterine trouble, an intra-uterine injection of corrosive sublimate [1-2000] was given after the extraction, and the placenta was expressed. Ordinarily when corrosive sublimate is used here another injection of water is given to guard against poisoning, but during the injection of the sublimate the patient had a collapse with unconsciousness, etc.; the irrigation was stopped and means taken to relieve these alarming symptoms. Within half an hour she recovered and then the uterus was washed out with water. The next three days the temperature fell to 37°C.; On the second day she had diarrhœa, on the fourth stomatitis, and on the sixth she suddenly died. The autopsy showed signs of the poisoning, as did also chemical examination.

Very truly yours, I. LOUIS, M.D.

THE IMPROVEMENT SOCIETY'S REPORT ON THE MASSACHUSETTS MEDICAL EXAMINER SYSTEM.

GLOUCESTER, March 6, 1886.

MR. EDITOR,— Apropos of Dr. Fifield's paper on the Medical Examiner System, and the report of a committee to the Boston Medical Improvement Society on the same subject, both published in the JOURNAL, I would beg your readers to refresh their memories upon one case, the subject of criticism, by referring to the number of the JOURNAL for November 9, 1882, in which on page 436 *et seq.* is a very able paper upon the case in question by the Medical Examiner under whose notice it came.

Very respectfully, GEORGE B. STEVENS, M.D.

NORFOLK COUNTY, March 5, 1886.

MR. EDITOR,— I perceive on reading the report of the committee of the Medical Improvement Society on "Medical Examiners in Massachusetts," as published in last week's issue of the JOURNAL, that an oversight was made by the committee in not discovering that the *second* instance of incompetency investigated by them occurred under the *coroner* regime, and consequently if there was any failure of duty at the autopsy it did not lie at the door of the medical examiner. It may, however, be said of this case, in the language of Dr. Fifield concerning that other case of his, alluded to by the committee as the *fourth* instance, that "conviction and sentence of the criminal duly took place."

The reference by Dr. Fifield is without doubt to the celebrated case of Julia Hawkes whose dead body was found in Monatiquot river several years since, with a bullet hole in the head and a tailor's goose tied to the feet. As shown at the trial, the death probably occurred outside of Norfolk County. Very truly yours, MEDICAL EXAMINER.

[We understand that, as the committee was refused information as to the particular "instances" referred to in the paper of Dr. Fifield, its members did not feel at liberty to go behind the written words and surmise to which cases the criticisms applied, although there might have been no great difficulty in doing so.— ED.]

RELATION OF THE SPLEEN TO THE STOMACH.

AUGUSTA, ME.

MR. EDITOR,— The following suggestions in regard to the possible function of the spleen have occurred to me. Briefly recall to mind something of the anatomy of the spleen, especially in connection with the stomach.

Situated as it is in the left hypochondriac regions embracing the cardiac end of the stomach and held in position by the gastro-splenic omentum and suspensory ligament, its function would naturally be closely related with the stomach. Having no secretory duct to indicate its function, it is classed by anatomists with the ductless glands, and its office in the economy appointed alone on theory. The spleen is composed of such elastic structure as to allow of the considerable changes occurring in its size.

Its increase during and after digestion is a well-known fact. This we know to be the result of an engorgement of blood. As to its blood supply we need but to recall the large size of the splenic artery and the great vascularity of the organ itself. This blood is returned through the splenic vein which constitutes the largest branch of the portal vein. The splenic artery is in such relation, by its origin from the cœliac axis and by branches to the stomach, as to be capable of greatly influencing the blood supply of that organ.

We find its nerve-supply, the pneumogastric and semilunar ganglia, such as to render it in close sympathetic relation with its neighbor, the stomach, controlled by the same centre.

By a controlling nerve centre closely allied to that of the stomach the condition of the spleen appears to be regulated correspondingly. By this nerve-system the digestive turgescence seems explicable, and may it not be in ratio inversely to the flushed condition of the gastric membrane during its activity?

In view of the fact that the spleen may be wholly removed from an animal without any obvious changes in the economy taking place, might we not with propriety ask, is not its office solely mechanical and one of great importance, namely, that of a regulator of blood supply to the stomach? It seems obvious that such a regulator is necessary to an organ subject to such varying conditions — at one time the receptacle of hot drinks, tea and coffee, taken at a temperature little below scalding, and again of large draughts of ice water. What is to prevent serious congestion or depletion, or to afford a ready supply in aiding the digestion of a hearty meal, if not this balancing medium?

So we offer this special and sufficient function of the spleen — an organ attendant to the stomach, a diverticulum of its blood supply, standing ever in an inverse relation in this respect to the needs of the stomach.

Yours truly, H. L. JOHNSON, M.D.

FT. BIDWELL, CAL., Feb. 14, 1886.

MR. EDITOR, — I am engaged in the preparation of a "Compendium of the Surgical History of the War of the Rebellion," designed as a hand-book for military surgeons, and desire to consider at some length, "Injuries of the Bloodvessels," the remote effects of gunshot wounds in general, and the ultimate results as regards the functional utility of the limbs treated by conservation and excision in particular. Inasmuch as many of the survivors have doubtless come under professional observation at this late date, it is hoped that the observers will render a service to military surgery and to me personally, by communicating unpublished data, which will be gratefully acknowledged.

Respectfully, GEORGE M. KOBER,
Act'g Ass't Surgeon U. S. Army.

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 27, 1886.

Deaths reported 2,047: under five years of age 720; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 268, consumption 347, lung diseases 343, diphtheria and croup 120, whooping-cough 31, scarlet fever 20, typhoid fever 21, diarrhœal diseases 21, malarial fever 29, cerebro-spinal meningitis, nine, erysipelas five, small-pox four, measles four, puerperal fever four. From typhoid fever, Philadelphia eight, Baltimore three, New York and Brooklyn two each, District of Columbia, Lowell, Salem, Taunton and Malden one each. From diarrhœal diseases, New York seven, Brooklyn five. Boston three, Cincinnati and Lowell two each, District of Columbia and Holyoke one each. From malarial fever, New York 13, Brooklyn four, Baltimore three. From cerebro-spinal meningitis, New York three, Baltimore two, Philadelphia, Worcester, Fall River and Taunton one each. From erysipelas, New York three, Philadelphia and District of Columbia one each. From small-pox, New York four.

Cases reported in Boston: diphtheria 24; scarlet fever 21; and typhoid fever three.

In 103 cities and towns of Massachusetts, with a population of 1,339,159 (population of the State 1,941,465), the total death-rate for the week was 14.83 against 15.96 and 16.14 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending February 13th the death-rate was 25.1. Deaths reported 4,024: infants under one year of age 882; acute diseases of the respiratory organs (London) 584, whooping-cough 188, measles 67, diarrhœa 46, fever 43, scarlet fever 30, small-pox (Liverpool) three.

The death-rates ranged from 14.7 in Huddersfield to 30.9 in Preston; Birkenhead 23.5; Birmingham 19.6; Hull 18.3; Leeds 19.2; Leicester 15.3; Liverpool 24.4; London 24.9; Manchester 29.1; Nottingham 20.8; Sheffield 18.6; Sunderland 22.1.

In Edinburgh 18.7; Glasgow 29.8; Dublin 38.6.

For the week ending February 13th in the Swiss towns, there were 31 deaths from consumption, lung diseases 27, whooping-cough 10, diphtheria and croup seven, small-pox two, measles one.

The death-rates were: at Geneva 13.3; Zurich 28.6; Basle 18.5; Berne 24.6.

The meteorological record for week ending February 27, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps: —

Week ending Saturday, Feb. 27, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 27, 1886, TO MARCH 5, 1886.

WILLIAMS, J. W., major and surgeon. Ordered for duty as post surgeon, Vancouver Barracks, Washington Ter.

MUNN, C. E., captain and assistant surgeon. Ordered for duty as post surgeon, Fort Cœur d'Alene, Indian Ter.

WOOD, M W., captain and assistant surgeon. Ordered for duty as post surgeon, Fort Walla Walla, Washington Ter. S. O. 31, Department of Colorado, February 26, 1886.

WM. S. TREMAINE, major and surgeon Leave of absence extended six months on surgeon's certificate of disability. S. O. 50, A. G. O., March 2, 1886.

HENRY MCELDERNY, major and surgeon. Leave of absence extended one month. S. O. 49, A. G. O., March 1, 1886.

WM. G. SPENCER, captain and assistant surgeon. Ordered for duty at Fort Yates, Dakota Ter. S. O. 17, Department of Dakota, February 23, 1886.

To be assistant surgeons with the rank of captain after five year's service, in accordance with the act of June 23, 1874.

ARTHUR, WILLIAM, H., assistant surgeon, February 18, 1886.
BUSHNELL, GEORGE E., assistant surgeon, February 18, 1886.
BIRMINGHAM, HENRY P., assistant surgeon, February 18, 1886.
WYETH, MARLBOROUGH C., assistant surgeon, February 18, 1886.

Circular A. G. O., March 1, 1886.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. OBSTETRIC AND GYNÆCOLOGICAL SECTION. — There will be a meeting of this Section at the large Medical Library Room, 19 Boylston Place, on Wednesday evening, March 17th, at 7.45 o'clock. Communications: Dr. W. S. Brown, of Stoneham, "Gynæcological Hints and Hobbies." Dr. S. W. Driver, of Cambridge, "Obstetric Gleanings; or Expedients and Mistakes." Dr. R A. Kingman will exhibit an Axis Traction Appliance for Simpson's or Braun's forceps. Refreshments after the meeting.

JAMES R. CHADWICK, M.D., *Chairman.*
ROBERT B. DIXON, M.D., *Secretary.*

ERRATUM.

In an article by Dr. F. N. Otis, Feb. 18, 1886, on "Limitation of the Contagious Stage of Syphilis," etc., p. 148, 1st column, Mr. Hutchinson should be quoted as saying that "no *minified* transmission of syphilis is possible."

THE ÆTIOLOGY OF LATERAL CURVATURE.[1]

BY E. H. BRADFORD, M.D.
Visiting Surgeon, Boston City Hospital.

THE theories advanced to explain the phenomena of lateral curvature are the following:—

1. That the distortion is due to unequal muscular action as is true in torticollis. 2. That the cause is to be found in an inequality of growth of different portions of the vertebræ as if the affections were to be classed as a localized unilateral hypertrophy. 3. That the distortion is the result of superincumbent weight acting upon a faulty condition of the spinal column.

Of the two first it may be said that they do not explain satisfactorily the conditions presented by many cases where no evidence of muscular contraction can be found, or any other reason to justify a belief in the existence of a freak of growth. Furthermore, if a series of cases be collected and arranged according to their severity, it will be found that in the lighter cases (differing apparently but in degree from the severer ones), no abnormity of growth in the spinal column is present.

To demonstrate, if possible, the truth of the third of these theories the following series of observations were made, for which I am indebted to the assistance of Professor Dwight and Drs. Mixter, Conant, Newell, and Burrell. Observation I. The spinal column of a full term infant was removed, leaving the skin, superimposed muscles and ligaments intact, but removing the ribs. It was found that although the column was more flexible than in children, adolescents, or adults, rotation was not readily brought about by simply pressing the two ends toward each other, holding each end in the hand; the amount of lateral deviation, that is, curving sideways, without rotation of the bodies, was not great, though much greater than in well-grown spinal columns. The most noticeable effect of pressing the upper part downwards was to cause a bending with the concavity forwards; bending with the concavity backwards was possible only to a comparatively slight degree. Rotation was easily produced by twisting the spine.

Observation II. The body of a young female adult was hung by the head with the head fixed and the body free from the floor, the skin of the back having been dissected off; long pins were driven in the occiput and in the spinous processes of the different vertebræ; a thread with a weight was hung from the pin in the occiput, long enough to touch the floor, and a second thread with a piece of chalk attached was hung successively from the pins inserted in the different spines and from the sacrum. The pelvis was then twisted forcibly and the arc marked off on the floor by the piece of chalk, as suspended from the different pins, was measured from that point in the circle indicated by the plumb line, hung from the pin inserted in the immovable head.

The figures are as follows, measured from the line from the occiput.

Are described by a line from				sacrum	150°
"	"	"	"	axis	60°
"	"	"	"	first dorsal	83°
"	"	"	"	third dorsal	100°
"	"	"	"	sixth dorsal	118°
"	"	"	"	twelfth dorsal	139°
"	"	"	"	third lumbar	136°

[1] Read before the Boston Society for Medical Improvement, March 8th, 1886.

While these figures are only approximative, as the amount of force used in the successive twistings was not measured and presumably not the same, yet they indicate that the amount of rotation possible is greatest in the dorsal region, leaving out of count the twisting possible in the atlanto-axoid articulation. The three or four upper dorsal moved together; the greatest rotation appeared to be in the third lower dorsal; lateral deviation (that is, without rotation) was possible only in the lower dorsal vertebræ. Pressure made on the floating ribs appeared to have little effect in twisting the vertebræ, but pressure on the thoracic ribs appeared in a measure to affect the line of the spinal column. Some play in the costo-vertebral articulation existed, but beyond that point pressure exerted on the ribs was transmitted to the column.

Volkmann[2] found that in life the greatest possible twist of the whole body, including that occurring in the hip joints, was 144°, so that the figures here given are overstatements of the possible physiological limits of rotation. This is also somewhat greater than that indicated by the facets of the disarticulated vertebræ, which would show that if the joints were firm there would be absolutely no rotation in the lumbar region, little in the cervical, except in the atlanto-axoid articulation, and not much in the dorsal region. A certain amount of laxity in the articulation allows more play than would be supposed by the structure of the bones. This was evident on forcibly twisting the cadaver.

The amount of forward and backward motion possible in an adult is much less than would be supposed. This is apparent on inspection, and has been accurately measured by Meyer.[3]

Observation III. The whole spinal column of an adult male, a dissecting-room subject, was taken, including a portion of the pelvis, and the base of the cranium. The larger muscles were removed, but the ligaments and smaller muscles were kept. The pelvic sacrum was firmly held in a vice and a box was secured on the cranium by passing a rod, firmly secured to the box down into the medullary canal of the cervical vertebræ; the box was then secured so that it would move up and down, but not laterally; weights were placed in the box.

It was found that the spinal column could bear a considerable weight without yielding to any noticeable extent. As the amount was increased a curvature with concavity forward was seen, which increased as the weight was increased up to eighty-four pounds. No rotation of the vertebræ was observed as long as the weight bore down directly, but rotation on the lower dorsal and lumbar region was seen when any lateral deviation was made in the cervical region; the amount of rotation or deviation was, however, very small as compared with that possible in children.

None of these experiments approximately reproduced the conditions to be found in life, as the attachments of the ribs had been severed and the viscera removed. Furthermore, the spinal column in the adult is much less flexible than that of a child or adolescent, when lateral curvature is usually observed.

Observation IV. The body of an infant of a year was prepared in the following way. The thighs were amputated near the hip joints and the pelvis fixed upon the remaining stumps and secured by means of nails on

[2] Virchow's Archiv. 1872.
[3] Die Statik und Mechanik des Menschlichen Knochengerüctes, page 210. Virchow's Archiv. Bd. xxxv, page 225. Ibid. Bd. xxxvi, 1866, page 144. Ibid. xxxviii, page 15.

a board, long pins were passed laterally through the pelvis and secured to the board by means of hooks, and the whole pelvis then imbedded in plaster-of-Paris.

The board to which the body was secured was then placed on a stand with four upright rods attached at the four corners, to which rods a flat board was attached so that it would slide smoothly up and down. The child's trunk therefore was placed between two boards, one being fixed and the other pressing down upon the child's head. To keep the head in place it was inserted in a tightly-fitting tin cylinder which was fastened to the under surface of the board. Weight placed upon the upper board, (sliding as it did freely upon the uprights) brought a downward pressure upon the child's head and shoulders. To make the latter more even a wooden collar was placed around the neck resting on the shoulders. Long pins were then inserted in the spinous processes of the vertebræ so that rotation could be more readily noticed. To check the falling forward of the neck a cord was placed around the neck and fastened at the side to the uprights, acting as a check, just as in life the longer muscles of the back would act in keeping the body erect.

Downward pressure upon the upper board caused the child's back to bend backward (convexity backward). When carried beyond a certain point the column would bend sideways with marked rotation, with the changes usually noticed in the ribs, flattening on the side of the concavity and projection on the side of the convexity. This projection was most marked in the middle and upper dorsal region, but the amount of greatest rotation appeared to be in the lower dorsal region. If the angle of downward pressure was changed, or if the pelvis was tipped so as to cause a curve in the spinal column the effect of downward pressure was more marked.

Rotation of the vertebræ was, of course, readily produced by lateral pressure twisting the spine; and on removing all downward pressure, by placing the cadaver in a horizontal position rotation and curvature in the dorsal region was easily made by twisting the pelvis and holding the head fixed, or *vice versâ*, the axis of the head and pelvis being kept the same.

Although a well marked scoliosis was thus artificially produced, attended by the characteristic flattening of the ribs on the side of the concavity and projection on that of the convexity, yet a more careful examination appeared to show that although this was the result of downward pressure, it was downward pressure not exerted in a perfectly vertical direction; for although the force was applied properly, yet it was not possible to prevent some play in the cervical region, from which it resulted that the force fell obliquely upon the under portion of the spinal column, causing curvature and necessarily rotation.

If it were practicable to apply a force directly downward and transmit it through the cervical and upper dorsal region without deviation, the effect upon the lower dorsal region would be to cause an antero-posterior curvature.

The lateral curvature therefore results from downward pressure, but downward pressure applied obliquely upon some portion of the spinal column. Rotation follows from the anatomical structure of the interlocked vertebræ, it being possible for them to rotate slightly, while the amount of tipping sideways (without twisting) which the articular facets permit is much less.

Rotation takes place with the vertebral bodies directed toward the convexity and the spine to the concavity for the reason that the former being larger, are unable to be crowded into the smaller space of the concavity, and are pushed in the direction where there is more space. Perhaps also, as has been pointed out by Judson, the fact that the bodies are free while the spines are held by muscles may give the former more freedom in movement.

From the above facts the following generalizations may be made:—

The effect of the weight of the thorax on head and shoulders would be, if applied in a vertical direction, to bend the spinal column forward and backwards, but in flexible spines the superincumbent weight rarely falls directly, and curvature follows. This is at first a physiological process, but it subsequently becomes, by the alteration in the shapes of the bones under altered pressure, a pathological change.

The extent of the curve, and the situation of the curve will be determined by the attitude habitually taken by the individual, and perhaps also by a difference in the resisting power in different parts of the column.

The injurious effect of superincumbent weight in curving the spine, is increased by the obliquity of the pelvis, or the inclination of the shoulders so frequently taken by persons of weak muscular systems in sitting sideways and leaning. The curve is usually in the dorsal region, with the right shoulder raised, as the majority of people are right-handed.

The distortion is one of growing years, and is more common to girls than boys, for two reasons, namely, that at the age when lateral curvature is usually seen first, girls grow more rapidly than boys, and their muscular system is less well developed, from the customary of life habits of girls in society. The effect of superincumbent weight upon a yielding spine in adult life, after the vertebræ have ceased to grow, is to cause an increase in the antero-posterior curve of the back.

The matter may be summed as follows:

The deformity known as lateral curvature is the result of several factors, the chief being,

1. Superincumbent weight.
2. Faulty attitudes due usually to muscular weakness.
3. A condition of the bone structure of the spine incapable of resisting the effect of weight, analogous to that known as rickets of adolescence.

SIX CASES OCCURRING IN PRACTICE.

I. SPASMODIC ABDOMINAL CONTRACTIONS. II. PARALYSIS OF ARMS IN CONGENITAL SYPHILIS. III. TWO CASES OF EMPYEMA, (1) AT EIGHTEEN MONTHS, (2) AT FOUR YEARS. IV. DOUBLE PLEURITIC EFFUSION AT THIRTEEN YEARS. V. SIMULATED VESICAL AND RENAL CALCULUS AT TEN YEARS.[1]

BY T. M. ROTCH, M.D.

SPASMODIC CONTRACTION OF ABDOMINAL MUSCLES.

J. M., a man twenty-eight years of age, presented himself for treatment at the City Hospital, January 12th, 1886. He has always been strong and well, but since beginning to work as a barber last spring, has

[1] Read before the Boston Society for Medical Observation, February 1, 1886.

been very nervous. In April, 1885, he began to have attacks of spasm of the abdominal muscles. The contractions are irregular in force and interval of rest, but have been continuous and have incapacitated him from work; at first he had some control over the attacks, now he has none. The spasms occur nearly every day, and he feels that they are coming on a short time before they begin. The intervals are usually about half a minute. When he has succeeded in controlling one or two spasms the next one is increased greatly in severity.

He is slightly constipated, and since the attacks began has lost in strength somewhat and had a poor appetite. On physical examination nothing abnormal was discovered. He behaves, when observed during an attack, as though some one had struck him in the epigastrium.

He was treated with Fowler's solution, and on January 21st, reported himself as improving.

APPARENT PARALYSIS OF BOTH ARMS IN A BABY WITH CONGENITAL SYPHILIS.

C. S., a boy six weeks old, was brought to the Children's Hospital, April 7th, 1885, by his mother, a Swede. The mother has always been well and strong, according to her own account, and has never had any miscarriages, effloresence on skin, sore throat or anything which would point towards her having been infected by syphilis, and, on examining her, nothing abnormal could be found: she is strong and healthy-looking and manifests a desire, for the sake of her baby, to answer all questions freely. She has had no other children, and states that the father of the child had a sore in April, 1884. The child is breast fed and was healthy at birth. When one week old the mother says that the child had a bulbous eruption coming out on the soles of the feet, legs, palms of hands, arms, body and face, and began to have snuffles. April 4th, the left arm was noticed to be paralyzed. On examination the face was found to be covered with reddened patches, ulcerations and crusts. The arm hung helpless by the side, and the child seemed to be sensitive to the touch and to have pain.

The oleate of mercury 20 per cent. was ordered spread on a flannel abdominal band. When seen on the 14th, the right arm was also helpless, and the mother stated that the inunction had not been used much, as it caused excoriation. The ointment was then reduced in strength one half and hydrargyrum cum creta, one grain, given three times daily. In three days the paralysis of the arms disappeared, though the other symptoms continued. April 21st, the eruption had disappeared almost entirely from the face, but as the snuffles continued the mercury was increased to four grains daily; this had to be reduced to three grains later as it caused a slight diarrhœa. May 12th, the snuffles disappeared; the child was then not seen again until November 15th, when it presented gummata of the anus, a few papules on the body and a slight squamous effloresence on the soles and palms.

The previously mentioned mercurial treatment was then renewed, and by December 10th, all the lesions had disappeared excepting the squamous eruption on the hands and feet. The child at present looks well and strong, and is cutting its incisor teeth.

This case is of interest, first on account of the apparent freedom of the mother from syphilis, while the child was undoubtedly syphilitic: second, as showing that hereditary syphilis in not necessarily an atrophic disease, where the child can have good breast milk; (this child always looked particularly well nourished:) and finally the apparent cause of the paralysis. The possibility of the paralysis being poliomyelitis anterior acuta was considered but hardly seemed to cover the case, both arms being affected and entire relief taking place in three days after the use of mercury was properly carried out (of course it might have been essential paralysis but it is not probable.) A central syphilitic lesion was then thought of, but the rapid recovery of the paralysis before the efflorescence, or snuffles had begun to be affected seemed to show that a central lesion did not exist: the evident pain manifested by the child when the arms were touched and the speedy disappearance of this sensitiveness together with the paralysis under mercurial treatment, pointed towards a local trouble in the arms themselves, which causing pain on motion, the child did not choose to lift or use its arms. No traumatic history could be obtained; rheumatism occurring at six weeks of age and affecting the child in this peculiar way would be very unlikely, and I therefore supposed the case to be local inertia of the arms, from pain in the bones, resulting from that disease of the bones which occurs in hereditary syphilis and described by Wegner in Virchow's Archives, 1870, vol. 50. This disease was formerly called Parrot's disease, and supposed to be incurable until it was discovered to be one of the manifestions of syphilis. Roques describes a similar case, where the mother was apparently healthy but the child at birth had a pemphigoid eruption which disappeared under antisyphilitic treatment in a few weeks. At two months however paralysis of the arms occurred with pain and crepitation at the upper end of the humerus; antisyphilitic treatment was renewed and the symptoms passed off. Millard also reports a case where one arm was affected.

I thought that it might be of interest to the society to compare these plates showing the disturbance in the bones in Hereditary Syphilis, in Hereditary Cretinism, and in Rachitis.

In the fœtal skeleton the long bones are cartilaginous and the process of ossification is intracartilaginous. As the cartilage changes to bone the cartilage cells increase in number and are closely packed together: then comes the area of osteoblasts, then the calcareous matter, and deeper down in the ossified portion are the blood-vessels running in from the periosteum.

The epiphysis of the bones of the arm are still cartilaginous at birth and they remain separated from the bone shaft for some time by a narrow cartilaginous layer. It is in this cartilaginous separating layer that certain changes are seen in congenital hereditary syphilis, as will presently be shown in the wood-cut, and Wegner's colored plates of fresh specimens show also the characteristic change of appearance of this layer from its normal color to a yellowish-white: the pain and sensitiveness in these cases of local syphilitic paralysis are probably caused by a consecutive low grade of periostitis; this same cartilaginous layer is also a marked feature in the changes which take place in the bones of congenital cretins and in rachitis. I will also call the attention of the society to these preparations of sections of bones, made by Dr. Wm. F. Whitney, which beautifully illustrate the difference of proportion between the cartilage and bone in the normal child at birth and the cretin, the cretin bone being

shorter and the cartilaginous epiphysis greatly out of proportion to the shaft; the cretin bone also showing the above spoken of cartilaginous layer or zone very narrow in comparison with the same layer in the rachitic bone.

Dr. Ernest Zeigler in his Lehrbuch der Allgemeiner und Specieller Pathologische Anatomie und Pathogenese: II. Theil, 2 Hälfte, represents these different conditions of the bones in four wood-cuts. No. I, illustrates diagrammatically the normal endochondrial ossification. No. II, the endochondrial ossification in a new born cretin. No. III, the endochondrial ossification in hereditary syphilis of the new born, with its misplaced foci of calcification, misplaced medullary spaces and islands of calcification. No. IV, the rachitic endochondrial bone formation. The literature of this osteochondritis syphilitica is: Wegner, Virch. Arch. 50. Bd. Waldeyer u. Köbner, ib. 55. Bd. Hoab, ib. 65. Bd. Veraguth, ib. 84. Bd. Stilling, ib. 88. Bd. Parrot, Archiv. de phys. IV. 1872; Cornil et Ranvier Man. d'histol. pathol. II. 1881. Kassowitz, Die Normale Ossificat. u. s. w. Wien 1881. Müller, Virch. Archiv. 92. Bd.

(Dr. Rotch then showed in addition to the colored plates of Wegner and the wood-cuts of Zeigler, colored plates of normal and rachitic bones by Kassowitz, and a photograph of the new born cretin from which Dr. Whitney had prepared the section of bone.)

III. EMPYEMA.

In reporting these cases of empyema, my idea is not to draw any especial conclusions from them or to give the records in detail, but to pick out some of the points which may be of use to others in the daily treatment of this class of cases, where the sudden changes from comparative quiescence of symptoms, with almost normal temperature, to heightened temperature and a serious aspect of affairs, is not of uncommon occurrence.

I have personally had only eight operative cases of empyema under my care, and with the exception of the two cases which I am about to report, and one other, simple incision, drainage and daily washing out with carbolic acid and water were employed, and where no complicating disease existed, they did well and ultimately recovered; but I should say that the course of the disease was decidedly prolonged in comparison with the time taken when antiseptic methods were employed. Various tubes and appliances for securing the tubes were tried from time to time, resulting in finding that a safety-pin passed through a rubber tube, the easiest to manage, and the most simple. I also found that two tubes were preferable to, and more likely to work well than one, and that the size of the tube was determined by the individual width of the intercostal space, the largest which could be introduced into the cavity without being pinched by the ribs, and thus interfering with the flow of pus, being the best. The cases now under consideration were treated in exactly the same manner, and, it is believed, with equal care as to antiseptic details, such as cleanliness, and thorough disinfection of hands, instruments, and dressings; both cases were in private families, and both were subjected to the same climatic changes in Boston during the spring of 1885; both recovered completely, without deformity, and with apparently sound lungs, so that they show how, under the same conditions, the disease can vary in its course: Case I being short, fifty days; tube in twenty-four days; Case II being long, three months; tube in sixty-seven days.

CASE I. A boy, eighteen months old, well-developed; always well until April 26th, 1885, when he was suddenly attacked with fever, pain, and restlessness. Temperature 102°, pulse 160, respiration 60; no vomiting or nervous symptoms. April 27th, temperature 103°, respiration 80; grunting in character; decubitus right side, child screaming with pain when turned on left side; slight cough; auscultation and percussion of heart and front of chest normal; resonance slightly diminished in right back; no râles or bronchial respiration; left back normal.

During the next few days, numerous fine, moist râles were heard over the right back, and dulness gradually developed over the back, the axillary region, and apex in front.

May 8th. The dulness changed to flatness; the râles disappeared, and the respiration was scarcely perceptible in the area of flatness behind. Aspiration was performed in the seventh interspace, at the angle of the scapula, and three ounces of clear, inodorous pus removed, when the resonance became fair in lower back, with tubular breathing and a few fine râles; the temperature then went down from 101 to 99.5°, the respiration from 80 to 60, and the child was much brighter.

May 11th. The flatness returned, and four ounces of rather thicker pus was removed with the aspirator, and one ounce on the 14th.

May 18th. The temperature was 102.4°, and as the fluid continued to return, ether was given, and (Dr. Ruddick and Dr. H. L. Burrell being present) an incision was made in the eighth interspace in the anterior axillary line, one and a half inches long; two or three ounces of odorless pus escaped, two tubes were introduced one inch into the chest, secured by a safety-pin, and an antiseptic dressing applied.

May 19th. Comfortable until the afternoon, when he began to be restless and to have a heightened temperature; and on the 20th, was reported to have cried all night, and was found to have a temperature of 102°. The dressing was changed, and clots of somewhat tenacious pus, about a handful, were washed out with a solution of corrosive sublimate, 1 to 10,000; a pint of the solution was used, and a block-tin sound to break up the clots; the tubes were left one-half inch in the chest. The temperature then fell to 98.5°, and the child began to gain and to have a good appetite.

On the 29th, one of the tubes was removed; the dressing was only changed when there was evidence of soakage, when it was done at once. On the 31st, as there were only a few drops of pus on the dressing, and these of rather a serous character, the remaining tube was removed, and the child walked out and rapidly regained its strength; on the 5th of June, however, the temperature went up to 102° and the tube was replaced, considerable pus flowing out. On June 11th, the tube was permanently removed, and later in the summer, the child was reported to be perfectly well, the lung apparently being normal on auscultation and percussion.

There is nothing but a normal course to record in this case, with the exception of the first forty-eight hours after the operation, when, instead of the temperature going down and the patient being comfortable, the old symptoms continued until relieved by washing out the cavity. This episode, however, is of considerable

interest in respect to the treatment of the case at the time of the operation, that is, whether the cavity should be washed out at once, to ascertain whether the pus is too thick to flow through the tube, or whether we shall take our chances of this occurring, as it is the exception, rather than the rule. In my former cases, where I always washed out at the time of the operation, I obtained entire relief to the symptoms at once, so that I was at first rather inclined to irrigate with a disinfectant in the antiseptic cases before adjusting a dressing; but the experience with reference to this formation of pus-clots, which came to me in Case II, seemed to show that the clotting can take place at any time, either before or after the operation; and that, therefore, it may be wise to wait for some sign that nature needs assistance in accomplishing an uninterrupted flow through the tubes, before introducing foreign matter into the thoracic cavity. The age of this patient, eighteen months, is also a point of interest in the case.

Case II. A girl, four and a half years of age, with a history of measles two years previously, and a chronic otorrhœa following, and lasting up to the time of the present attack; otherwise strong and well until April 15th, 1885, when, in the morning she was very well, and had a normal temperature, but later in the day, began to complain of pain in the sternal region, and when seen at 2 P. M., had a temperature of 103° (axilla), respiration 60, pulse 165, and nothing abnormal found on physical examination.

7 P. M. Temperature 104°. Dr. Minot in consultation; nothing abnormal discovered.

April 16th. Temperature 104°, pulse 165, respiration 66 (grunting in character); slight dulness in right axillary region and respiration rather tubular; urine passed involuntarily; mind clear; pain on being moved, and when placed on right side, cries out continuously until turned on to back.

April 17th. Respiration 84, pulse 165 (intermittent); slight cough; coarse, sonorous râles over both fronts; a little dulness in right back; auscultation and percussion, otherwise normal, excepting slight area of dulness over upper part of sternum. The child always refers her pain to the upper part of the sternum, on the right side. On the 18th, a few râles and dulness were found over the right front and sternum, and the heart's apex was a little to the left of the mammary line; also, a friction-sound was heard at the right edge of the upper part of the sternum, some dulness in the axillary line, and a few moist râles in the right back, with lessened percussion resonance, but no dulness.

By the 20th, the friction-sound had disappeared, bronchial respiration was heard at the right apex, in front and behind, and the dulness extended to the right back. Temperature 100 1-5°, respiration 84, pulse 165, regular.

Up to the 23d, the dulness was decidedly most marked in front, but by the 27th, there was flatness over the whole of the right lung, front and back, with bronchial respiration. Temperature 100°; no cough. On the 30th, aspiration was performed in the seventh interspace, just outside of the angle of the scapula, and one ounce of thick pus withdrawn.

May 2d. Pulse 165, respiration 60, temperature 101°. Ether was given (Dr. Minot and Mr. J. Perkins, interne at the Children's Hospital, being present), and with carbolic acid spray, and the antiseptic precautions employed in Case I, an incision was made in the eighth interspace, in the posterior axillary line; one pint of inodorless pus escaped, two tubes were introduced, and the antiseptic dressing applied. 6 P. M., temperature 98.5°.

May 3d. Reported to have had a restless night. 8 A. M., temperature 101°, pulse 165, respiration 60; tube found to be pressed upon by the dressing; heart's apex in position; gurgling râles and cavernous respiration all over right lung, and in an hour or two, temperature 98 4-5°, pulse 135, respiration 45. The temperature then remained normal, and the patient steadily improved until the 12th, when she began to have an evening temperature of 102°, and respirations of 60; and as this continued for several days, the dressing was removed on the 15th.

Very little discharge was found on the dressing and no odor; a probe passed through the tubes entered the pleural cavity freely; Labarraque's solution 1-16 of water was then injected and ran in and out freely, very little pus coming out with a small amount of coagulated fibrin, and a few little blood clots; the dressing was then re-applied and the temperature found to be 99°; six hours later it went up to 103°; the dressing was then again removed, the tubes taken out and a block-tin sound introduced and gently moved about in the cavity; the Labarraque's solution was then again injected and some thick clotted pus came away; new tubes were introduced. May 16th, the child was screaming with pain and was reported to have had an almost sleepless night. Temperature 101°. Pulse 150. Respiration 50; the dressings and tubes were again removed and a female catheter attached to a fountain syringe was introduced between the ribs and Labarraque's solution injected; large dense tenacious clots (a basin full) then with great difficulty came through the wound; the clots did not merely look like those described in Case I, but it seemed as if some chemical reaction had taken place between the Labarraque's solution and the pus, rendering it a dense mass, which by no possibility could flow through a tube; the dressing was then re-applied, but although the temperature went down the child was restless and looked very badly, so that on the next day it was deemed best to remove the dressing and I then thoroughly washed out the pleural cavity with a solution of corrosive sublimate 1 part to 10,000 of water; a few more of the tenacious clots came away, the tubes were shortened one-half inch, and the child had the first good night which it had had for some time; the sternal pain disappeared; the temperature became normal and the child rapidly gained, there being occasional complaints of sternal pain and slight rises of temperature, easily controlled by changing the dressing and injecting the corrosive sublimate. May 27th, one tube was permanently removed, and the child walked for the first time. At times the tube had to be introduced further and again shortened. June 2d as there was only a little serous discharge and the child was doing well the remaining tube was removed, and two days later the auscultation and percussion was almost normal, excepting that the respiration was rather harsh at the base behind, and that there was a small area of dulness in the axillary line around the wound; three days later, June 7th, the child was looking badly and had a temperature of 103°, quick shallow respiration and pulse 160. Ether was given and the tube introduced, when two or three ounces of clear inodorless pus came away; the child then began to improve and to have a normal temperature, and was taken to Beverly on the 10th;

from this time, with an occasional bad day from the tube getting clogged, she grew stronger and played out of doors with, however, decided left lateral curvature and raising of the left shoulder. The tube was not removed but gradually shortened by altering the position of the safety pin, and on July 8th the tube was permanently removed by simply letting the wound close up around its pleural end and gradually push it out. The auscultation and percussion of the lung soon became normal excepting a slightly dull area around the wound; the lateral curvature soon passed off, having existed for two months. In December the child, who is passing the winter at the Lake of Geneva, was reported to be perfectly well, excepting that the chronic otorrhœa returns from time to time.

The points of especial interest in this case were the obstinate and unaltered dorsal decubitus lasting for weeks, the sternal pain and the unusual behavior of the pus when Labarraque's solution was used. It is also to be noted in this case that instead of being able to withdraw the tube at once when the discharge became serous, as is usually a safe procedure, I had to gradually shorten the tube from the outside allowing the cavity to close around it and finally push it out, for complete withdrawal of the tube always made the temperature go up. As to the fluid used in washing out the pleural cavity, corrosive sublimate is disinfectant at 1 to 10,000, is without odor, and so far as I know has not caused any symptom of poisoning when diluted to this extent; it was freely used in both cases.

IV. TWO ATTACKS OF PLEURITIC EFFUSION, CLOSELY FOLLOWING EACH OTHER, ON OPPOSITE SIDES OF THE CHEST.

CASE IV. A boy, thirteen years old, always well and strong, came to the City Hospital for treatment November 9th, 1885. Three weeks previously he fell into some water and was soaked from head to foot: in a few days he began to have pain in his left side and to cough. On physical examination the apex of the heart was found in the line of the epigastrium and there was flatness on the left side of the chest in front and behind nearly to the apex of the lung, with diminished respiration. November 23d he was aspirated and fourteen ounces of clear yellow serum withdrawn. November 28th the apex of the heart was found to be in position; there was lessened resonance on percussion and diminished respiration, but no râles; he had gained in weight and strength, had no cough and looked and felt well. He was then discharged and was perfectly well until December 23d when, without known exposure he had a chill and began to have pain in his right side, with dyspnœa and cough. He entered the hospital again January 7th, 1886, and was found to have flatness in the right side of the chest below a line corresponding to the angle of the scapula and the mammary line, the flatness extending a little higher in the axillary line.

In the area of flatness the respiration was much diminished; the vocal resonance and fremitus were decreased; the heart's apex was displaced to the left of the mammary line two c. m. At times a few moist râles were heard in the back, but these disappeared and the fluid after increasing for a few days, diminished; the boy gained in weight and strength and on the 28th is reported was feeling perfectly well. February 1, 1886, auscultation and percussion of the left lung were about normal; the apex of the heart was in position. Percussion of right lung fairly good; no râles; respiration diminished and about the same as was found in the left lung at time of second entrance to hospital. Vocal resonance and fremitus equal on both sides.

[Dr. Rotch exhibited the patient with the line of pleuritic effusion on the left side, and the heart displaced to the right; signs of the first attack, marked in red, and the pleuritic line on the right side and the heart displaced to the left; signs of the second attack, marked in blue.]

SYMPTOMS OF RENAL AND VESICAL CALCULUS IN A BOY TEN YEARS OLD.

A boy ten years of age had been moderately strong and well for some years; he has from time to time had incontinence since he was three years old, and at one time was for a short period unable to control his fæcal discharges; he had measles in the summer of 1885, and then although he did not have any especial symptoms, looked pale, lost in weight, and got tired easily, but he went to school and no complaint was made until November 2d, 1885, when he began to pass his water frequently, the desire coming suddenly; the water passed freely but caused pain referred to the end of the penis, and there was also irritation and pain about the prepuce. (No incontinence.) The prepuce was then retracted twice daily and carefully washed, and in four days the pain had disappeared from the prepuce and penis and was referred to the lower part of the abdomen; this pain was less when he rode on horseback, but increased when he sat down quietly. On the 8th he complained of considerable pain over the pubes. Pulse 81, temperature 98°, urine, sp. gr. 1,020; reaction acid; no albumen; heavy sediment of urates; under the microscope the whole field was found to be covered with uric-acid crystals.

November 9th. The urine was examined by Dr. Hills, with the following result: Color normal; specific gravity, 1021; reaction, acid; amount of sediment, considerable; urophiæn, slightly diminished; indican, normal; urea, normal; chlorides, normal; ether phosphates, normal; alkaline phosphates, normal; albumen absent; bile pigments absent. Sediment, normal amount of epithelium, some excess of mucus, an occasional crystal of oxalate of lime.

November 10th. Dr. Hills also found numerous uric-acid crystals.

December 1st. No sediment; neutral.

December 12th. Uric-acid crystals, and a few pus corpuscles; reaction, acid.

November 9th. The boy was then ordered to drink six or seven tumblers of Belmont Spring Water daily, with two or three grains of bicarbonate of soda in each tumbler, and on November 12th, he was restricted to a liquid diet. He, at times, had spasmodic pains in the bladder before and after passing his water, and attacks of vomiting and diarrhœa. The amount of the twenty-four hours' urine was about twenty ounces.

November 21st. The urine contained no uric acid, and he was without pain, still, however, passing his urine frequently. The soda was simply used to the extent of rendering the urine less acid.

December 7th. He complained of spasmodic anal pain and irritation; nothing was found on examination, and these symptoms were relieved in a few days by enemata of sweet oil.

December 9th. He was reported to have attacks of

pain in the region of the bladder, so severe, that his parents said that he rolled on the floor in agony, and he was confined to the bed for several days, with pain and frequent micturition. Uric acid in urine.

December 13th. Ether was given, and he was carefully sounded by Dr. E. H. Bradford; nothing abnormal was detected, excepting a slight feeling of resistance at the neck of the bladder, and a small adhesion on one side of the prepuce, which was torn away. The boy came out of his ether well, and for the next few days, seemed better and took solid food (for about twenty-four hours after being sounded, he had great pain on passing his water). The paroxysms of pain gradually grew less, and disappeared on the 19th.

On the 24th, he went out to drive, and he seemed to be improving, although considerable pus was found in the urine, but from the time of the sounding, no uric acid was found in the urine.

On the 26th, he had nausea, pain in right side of abdomen, passed his water frequently, though without much pain, was fretful, and in bed all day, and in the middle of the day, his temperature went up to 104°.

December 27th. Temperature 103.5°; too sick to get out of bed, drowsy, so weak that he can hardly stand; in the night, very restless, and passed a great deal of urine.

December 28th. Feels better, but pain and tenderness continue in right side, and there is some tenderness on pressure over the pubes.

December 29th. Dr. Hills reports as follows: Urine, color pale. Reaction, acid; urophæin diminished; indican diminished. Urea diminished; uric acid diminished; specific gravity, 1013; amount of sediment, considerable; chlorides normal; ether phosphates diminished; alkaline phosphates diminished; albumen, a trace; sugar absent; bile pigments absent. Sediment, considerable pus; an occasional blood-globule, a considerable number of small, round epithelium cells, which, so far as their size and shape afford any indication, may come from the tubules of the kidney, or from the prostatic portion of the urethra. As there are no casts, the epithelium without doubt comes from the prostatic portion of the urethra, and localizes the inflammation at this point. There is no excess of large bladder epithelium, so that the fundus of the bladder is apparently not involved. There are, however, a few cells resembling those found about the neck of the bladder, so that there may be a slight catarrh of the mucous membrane of this region. There is no evidence of any trouble in the kidney, or pelvis of the kidney, and no evidence of stone. The trouble is probably catarrh of the prostatic portion of the urethra, extending possibly into the neck of the bladder.

December 30th. Temperature 104° in the afternoon, and some pain in the back of the head, as well as the abdominal pain.

December 31st. Temperature 98°; feels better; appetite has returned; no pain on passing water. Two loose operations from bowels without pain. Pulse 75, regular. Less tenderness of abdomen. Passes a great deal of urine, but much less irritation about bladder. He then began to steadily gain in weight, strength, and color; the pain disappeared from the side, and the tenderness over the pubes grew less. He was up and about the house, but too much exercise or excitement at times caused a return of the pain.

January 19th. Dr. Hills reports as follows: Urine, color pale; specific gravity, 1012; amount of sediment, slight; albumen, slight trace. Chlorides normal; urophæin, indican, urea, uric acid, ether phosphates, and alkaloid phosphates diminished; sugar and bile pigments absent. Sediment, rather more small pus cells than normal; hardly more bladder epithelium than normal. Amount of twenty-four hours' urine says from three to four pints, but he is drinking about that amount of water daily.

January 31st. Has been steadily improving; slight tenderness over pubes, but no pain elsewhere, or in passing water. Urine normal. The boy is apparently well; the treatment has been, mainly, giving him large quantities of pure water to drink, on the ground that the great excess of uric acid in the urine might be causing, or rather exaggerating, his various nervous symptoms, and diluting the urine, apparently giving relief to this condition.

RECENT PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D.

SPREAD OF SMALL-POX BY HOSPITALS.

Further important observations in addition to those already noted, are published in a recent report by Dr. Murphy, late medical officer of health on the sanitary condition of Highgate and Hampstead as affected by the small-pox hospitals located therein. The conclusions arrived at are that in the four years, in which the Hampstead Hospital was closed, the houses immediately surrounding the hospital were attacked less than others in the parish. In 1884, when it was reopened these houses suffered three times as much as the rest of the parish. The same was also true of Highgate Hospital. While confessing that the distribution of the disease did not warrant him in expressing any definite opinion on the question whether the disease was spread through personal communication, or was aërially diffused, he considered that the evidence afforded, tended to show that their small-pox hospitals as at present constructed and managed were a means of disease to the neighborhood in which they were placed.

Hence the propriety of selecting sparsely settled districts, remote from habitations for the site of such hospitals.[1]

REGISTRATION OF NEW CASES OF SMALL-POX.[2]

Dr. S. Wolffberg suggests the following points of information as desirable to be ascertained in each new case of small-pox.

(1) Age; gender. (2) Date; Course and result of disease. (3) Has patient had small-pox before? When? Was it confirmed by a physician? (4) Was patient vaccinated? When? With what success? That is, how many scars to be seen at time of occurrence of small-pox? With what kind of lymph? (5) Was patient revaccinated? When? With what success? Are these traces of revaccination at time of occurrence of small-pox? With what kind of lymph was revaccination performed?

VACCINISATION.

Dr. Titeca[3] concludes that the principle of vacci-

[1] Local Government Chronicle, February 6, 1886, page 112.

[2] Centralblatt für Allgemeine Gesundheitspflege. Erstes heft, 1886. page 24.

[3] Étude sur la pratique de la Vaccine, ce qu'elle est; ce qu'elle devrait être, par le docteur Titeca. Bulletin de l'acad. r. de méd. de Belgique. 3 ser. t. xix. No. 6. 1885.

nation should be raised to the state or condition of an axiom; in other words, that it may be made perfectly protective. Dr. Warlomont has expressed a similar belief in his recent work.[4] They have crystallized this belief under the name of the school of vaccinisation (ecole vaccinisatrice), wherein they are in accord with the views of many others both in America and in Europe.

Dr. Titeca details at length the views of the vaccinists, and also of the anti-vaccinists. It is largely to the short-comings of the former, that the latter school owes its existence.

The following graphic picture of the defects of the vaccine employed, as well as of the operation itself, presents some of the most common reasons for failure.

"It often happens, especially in the country, that the agent intended for affording protection against variola, has nothing more of vaccine than the mere name. Whether sent out by the vaccinal institute, or by a committee of vaccination, or collected by the vaccinator himself, preserved in the shape of pulp, or upon points, plates, or in tubes, its efficiency is gradually weakened or lost in the desk or medicine-chest of the physician, who takes no care to renew his stock at the proper time.

"The operation is quite simple, three insertions on each arm, often one only, and that is all. Usually the child escapes further notice. The parents, or even the neighbors, take upon themselves the duty of informing the physician when occasion presents itself, that the vaccination has proved successful.

"More rarely . . . the child is brought, at a longer or shorter time after the operation, the visit resulting in the delivery of a certificate of vaccination, in the event of any vesicles or vaccinal scars, without regard to their number or appearance. In case of absolute failure the operation is delayed to a more favorable time.

"In point of fact this delay is often indefinite, the child being, in the opinion of its parents, *vaccinated*, as soon as it has received the required punctures. The case is still worse when it is left to the care of midwives or nurses."

The author therefore concludes that vaccination is in many cases *nothing but a deceptive operation performed with a hypothetic virus.*

The following questions are also discussed:

1. *No vesicle follows a given vaccination.* We are not therefore to infer that the subject is wholly insusceptible and abandon the attempt to secure a successful result. The quality of the vaccine employed, the method of operation and the possibility of a temporary insusceptibility of the subject are to be borne in mind. Of vaccinations made in 1882 at Utrecht and Groningen on subjects upon whom a primary vaccination eight days before had failed, there were respectively ninety-two and one hundred per cent. of successful results.

2. *One or more vesicles are developed.* Ought the subject therefore, *ipso facto*, to be regarded as having acquired immunity from small-pox? No. In discussing the question of multiple insertions, the author affirms the impossibility of determining beforehand the required number to protect a given subject. An old regulation of the German army required twenty insertions, ten in each arm.

In Holland, a modified vaccinisation has been practiced for a long time, ten insertions being made upon each subject, and the results classified in accordance with the number of good resulting vesicles, certificates being given to such as have more than five good vesicles. All others are submitted to a supplementary, or an auto-vaccination.

The following table gives the results of some supplementary vaccinations.

		Number of Supplementary Vaccinations.	Number Successful.	Average No. of Supplementary Vesicles.	Per cent. of Successful Results.
La Haye, 1881,	Subjects having 4 vesicles,	81	50	1-6	62
	" " 3 "	137	100	1-8	73
	" " 2 "	111	91	1-8*	82
	" " 1 "	76	72	1-8*	94
La Haye, 1882,	Subjects having 4 vesicles,	96	60	3	62
	" " 3 "	101	75	4	74
	" " 2 "	78	72	5	92
	" " 1 "	44	40	5	91
Utrecht, 1882,	Subjects having 4 vesicles,	45	28	1-4	62
	" " 3 "	53	34	1-8	64
	" " 2 "	90	60	1-9	67
	" " 1 "	52	34	1-9	65
Groningen, 1882,	Subjects having 4 vesicles,	4	2	1	50
	" " 3 "	29	13	1-5	45
	" " 2 "	43	34	1-8	79
	" " 1 "	44	37	1-9	84

* Or more.

Dr. Titeca criticizes this table, and reasonably asks if the subjects bearing four vesicles were submitted to revaccination, and gave fifty and sixty-two per cent. of success, would not those having five vesicles have nearly as successful results. In addition, Dr. Titeca gives the results of twenty-three primary vaccinations of children of various ages from three months to five years: twelve boys and eleven girls.

A second vaccination of these twenty-three children gave the following results:

7 successful, equal to 30.4 per cent.
6 partially, equal to 26 per cent.
10 unsuccessful, equal to 43.4 per cent.

Fifteen of these were vaccinated on the 6th or 7th day after the first insertion, with virus taken from the same subject (auto-inoculation).

In these the results were

6 successful, equal to 40 per cent.
3 partially, equal to 20 per cent.
6 unsuccessful, equal to 40 per cent.

In four cases vaccination was followed by a supplementary vaccination in from one to four months. None were successful; one partially, three unsuccessful.

In four others it was practiced at an interval of two, four, five and six years, something as follows; none successful, two partially, two unsuccessful.

A third vaccination was made upon four subjects, six to seven days after the second vaccination. Result: none successful, two partially, two unsuccessful.

The author regrets that for various reasons three cases which were wholly successful on the second trial could not have been submitted to the third vaccination. He also discusses the value of one or many cicatrices, and also the revaccination of persons who have had variola, citing the well-known figures of Marson, and the conclusive experience of the Prussian army.

With reference to the revaccination of persons who have had variola he states that 851 soldiers who had suffered from variola, were vaccinated at Antwerp in 1881, '82, '83, and '84, with almost 30 per cent. of success. (24.41 per cent in 1883; 33.5 per cent. in 1881).

[4] Traité de la Vaccine. Paris, 1883, page 283.

From a general review of the subject the author concludes that vaccination, to be perfectly protective, should be practised under the following conditions:

1. The employment of a vaccine virus which has lost none of its vitality.

2. The number of inoculations should be in accordance with the individual vaccinal receptivity, even to the extent of the exhaustion of that condition.

The first of these conditions is fulfilled by the use of living (*vivant*) vaccine, collected at the time of the operation; the second by the operation to which Dr. Warlomont gives the name of vaccinisation.

Every vaccination made in default of these conditions is deceptive, and to such faulty methods the anti-vaccination school owes its existence. Its faults and grievances will cease when the school of vaccination is recognized.

The author recommends the following practice:

1. Vaccinisation of infants within six months of birth.

2. Revaccinisation every ten years, when no epidemic is prevailing, and general revaccinisation in time of epidemic.

CREMATION.

The following figures show the extent to which this method of disposal of the dead has increased in eight cities of Italy since its introduction at Milan in 1876.

Years.	1876	1877	1878	1879	1880	1881	1882	1883	1884
No. burned.	2	15	16	27	45	75	69	82	113

Making a total of 444, of which number 332 were cremated in the two crematories at Milan, one built upon the plan of Gorini, and the other upon that of Venini.[5]

The new regulations in force since 1884 in the province of Milan with reference to cremation, provide for the prevention of the concealment of crime, very much in the same manner with the law enacted in Massachusetts in the following year requiring the addition of the signature of the medical examiner of the district where the death occurred, to that of the attending physician. The law in force in Milan requires an autopsy in case of the death of a person whose body is offered for cremation, provided the cause of death was uncertain, suspicious, sudden or violent.

No body can be cremated till twenty-four hours have elapsed from the time of death.[6]

THE VENTILATION, CLEANSING, AND DISINFECTION OF SEWERS.

In 1849, the Metropolitan Commission of Sewers, of London, following a series of experiments conducted by Sir Joseph Bazalgette, adopted a system of ventilating sewers by means of road-shafts with surface gratings. Latterly, complaints were made of noxious gases arising from these openings, which, it was claimed, were a nuisance, and injurious to health. In 1877, a Commission was appointed to consider the question of sewer ventilation in the metropolis. The results of their investigation have recently been published.

The origin of "sewer-gas" is accounted for by the decomposition of substances passing through, or deposited in the sewers, this gas being at a minimum at low temperature, and also when considerable quantities of water were passing through. The discharge of specially offensive trade refuse into them gives rise to additional objection, and the formation of more offensive gases. The difficulty of detecting such discharge in sewers is very great. Provision for frequent flushing in dry weather is suggested as a remedy of prime importance. With such a measure, special ventilation is imperative, otherwise running house-traps would be forced, and the health of inmates imperilled.

Large, heated chimney-shafts have also been suggested, and employed to a limited extent as a further remedy; also smaller shafts attached to houses, and extending to a considerable distance above the roof. Permanganic acid is also suggested for the purpose of disinfecting the sewers.[7]

In the same line of work, may be also named the experiments of Health Officer Wight, of Detroit, as detailed in a recent paper read before the American Public Health Association, at Washington. Several tons of sulphate of iron were used to disinfect the sewers of that city, and large quantities of sulphur were burned in pails suspended in the man-holes of the sewers.

The chief objection offered to this method was that it must afford only a temporary disinfection. One decided advantage was claimed, that of detecting imperfect traps and house-connections.

TRICHINOSIS.

Dr. Eulenberg reports the entire number of inspections of pork (Prussian) for the year 1884 as 4,611-689, of which number 2,624 were found trichinous, distributed in 904 districts. 250 sides of American bacon, and other preparations of American pork, were also found trichinous. The number of official inspectors was 19,521.

Inspection has been quite generally practised, with the exception of a few districts. There have been occasional requests for its abolition by some districts, in consequence of the tax imposed, and also an alleged unfairness in the treatment of city and country.[8]

Notwithstanding the vigorous inspection of pork, requiring an army of officials for its execution, outbreaks of trichinosis occasionally occur, like that of Emersleben, owing to the habit of eating raw meat. Dr. Rupprecht, therefore, proposes a law of still greater severity, which shall require the examination of thirty specimens from each animal by two inspectors acting independently of each other, with loss of position for carelessness in observation. Certificates of freedom from trichinosis to be exhibited with every sale of pork. In support of the necessity of more vigorous legislation, he cites certain localities where the hogs are constantly found to be trichinous.[9]

PUERPERAL FEVER AS A PREVENTABLE DISEASE: AMENABLE TO PUBLIC SANITATION.

Extracts from government decrees relating to physicians and midwives:

MINDEN, January 23, 1885.

Physicians and midwives are required to report every case and every suspicion of child-bed fever in their practice within twenty-four hours after knowledge of the same, to the police office, verbally, or in writing. Penalty, thirty marks, or imprisonment, for failure to report.

REGULATIONS FOR MIDWIVES FOR PREVENTION OF PUERPERAL FEVER.

DRESDEN, March 28, 1885.

1. Midwife to see patient; provide douche, metallic catheter, and bottle of weak carbolic acid, as provided in 7. 2. Midwife to keep on hand carbolic solution, glass specula, etc., to sell to patients. 3. Instructions as to clothing, etc. 4–6. Careful instructions as to cleansing of hands, arms, and finger-nails. Examination of perineum, bathing, etc. 7. Carbolic vaseline and solutions. Directions for using, and strength of solution prescribed. 8–13. Further instructions as to cleansing catheters, basins, and other appliances. No sponges allowed. 14 Midwife must neither wash nor cleanse the clothing of patient or child. 15–16. Regulations as to informing the district physician of the occurrence of cases of puerperal fever, or deaths from the same. 17. Instructions as to visiting patients ill with puerperal fever. Midwife not to attend another case under five days from last visit, and meanwhile, to wash arms, hands, and nails twice daily with five-per cent. carbolic solution, using soap and nail-brush, and cleansing cloths. Instruments also to be boiled in five-per cent. carbolic solution. 18 Midwife may visit the sick woman during these five days, but must not examine her. After this, may resume work under restrictions. 19. If other cases occur in her practice, she must go fourteen days without taking new cases, and follow the instructions of (17) as to cleansing, etc.[10]

POISONING FROM ARSENICAL PAPER.

A case of illness in a child, from the handling of arsenical glazed paper, is detailed, in which the symptoms were loss of appetite, loss of sleep, vomiting, and headache. The paper contained four centigrams of arsenic in sixty-three centigrams of paper. It was used by the child for the purpose of weaving toy-baskets.[11]

Clinical Memoranda.

POST-MORTEM IN A CASE OF MEASLES, WITH SOME REMARKS UPON THE TREATMENT OF PULMONARY ŒDEMA.

BY F. J. CANEDY, M.D., MEDICAL EXAMINER, SHELBURNE FALLS, MASS.

BEING called into one of the border towns of the county to make a post-mortem upon a young lady who had died, unexpectedly, while sick with measles, I received the following history from the girl's parents. Her age was twenty-four years, her occupation teaching in the district schools of the town, in which she had become tired, nervous and dyspeptic of late.

She came from her school in another part of the town on Friday, at the close of the school week, with a cough, headache, and general malaise, supposing that she had an influenza, but knowing that she had been exposed to measles.

Saturday and Sunday she was about the house with symptoms of a cold, but on Monday the catarrhal trouble having increased in severity, sneezing and redness of the eyes having come on, it was thought she was coming down with measles and she took her bed. Tuesday a physician from an adjoining town passing the house was called in, who diagnosticated the case as one of measles, and left some medicine. Wednesday the eruption having made its appearance upon the face, and the patient apparently doing well, word was sent the doctor that he need not call again, unless sent for.

Thursday night she was very restless and delirious, and the doctor was sent for Friday morning, who gave her bromide of sodium and tincture digitalis, which seemed to quiet her, though her pulse, as counted by her father, were one hundred and twenty or more during the day, her breathing very fast, and her heart beat with so much force as to shake her body and the bed upon which she lay, and so loud as to be heard across the room.

The doctor saw her again at 7.30 Friday evening, when he directed the medicine of the morning to be continued. At 8.30 the family thought her sleeping, and at 9.30 as she still remained in the same condition, they tried to rouse her, when they found she was in a stupor, her extremities growing cold, and much rattling in her lungs. At 10.30 she died.

Autopsy two days after death, assisted by Dr. Hiram Temple, of Charlemont. Body of a short light-complexioned girl, with much adipose tissue. The skin pretty much covered with the eruption of measles, especially upon the upper part of the body.

Subcutaneous fat two inches thick along the line of incision over the thorax and abdomen. Lungs occupied a rather small place in the upper and posterior part of the chest, the arch of the diaphragm being abnormally high, and upon lifting them up were found to be very heavy, displacing nearly their volume of water in a pail.

The trachea and bronchi were nearly filled with a serous fluid mixed with air bubbles, and upon inverting the lungs it ran in a stream from the cut end of the trachea. Upon cutting into the lung tissue, water flowed freely from the air vesicles, and dark venous blood from the vessels. The mucous membrane lining the trachea and bronchi was much reddened, thickened and softened, having much the appearance of a freshly-cut piece of beef steak. No points of broncho-pneumonia were found or deposits of any kind, the lungs having apparently been in a healthy condition previous to this attack of measles. The heart was rather small, with no evidence of disease, left side and arteries empty; right side, pulmonary artery and veins greatly distended with black tarry blood. Portal veins of the liver full of black blood. Mucous membrane of the stomach along the greater curvature reddened and swollen. Kidneys healthy.

Post-mortem examinations are made for medico-legal and diagnostic purposes, to add to our pathological knowledge and for therapeutic suggestions.

This was not a medico-legal case, and pathologically it adds nothing to pulmonary congestion and œdema, though, as we seldom have an opportunity to make a *post-mortem* in a case of measles, the evidence of the extent and severity of the tracheo-bronchitis, was interesting, and impressed forcibly upon my mind the fact, that measles are not always the trivial matter they are sometimes thought to be.

In the light of the *post-mortem* what were the therapeutic indications in this case? The cause of death was evidently congestion of the lungs and its consequent œdema; the acute bronchitis being the active cause of the congestion, and excessive deposit of adipose tissue a secondary factor of no small importance.

Treatment, to have been of any avail must have been some measure that would have relieved the over-distended right ventricle, and removed the venous stasis. Stimulants would have been manifestly useless applied to a heart beating with such force as to shake the patient's body, in its vain efforts to force the blood through the pulmonary vessels, and it seems to me that nothing but a *free venesection* from the arm, or perhaps better yet, a plentiful application of wet cups over the chest followed by hot flaxseed and mustard poultices to cover the thorax, frequently changed, with

[10] Deutsche Vierteljahrsschrift für öffentliche Gesundheitspflege, Bd. 17, Heft. 4, 1885.
[11] Wiener Med. Wochenschrift, 1885, No. 1.

a judicious administration of stimulants when the fatigued heart began to falter, offered the patient any chance.

These therapeutic suggestions are illustrated by the following cases: A large and very fat man, aged eighty-three years, who had suffered for many years with mitral insufficiency and latterly with cardiac dilatation, and shortness of breath upon exertion, had been down with influenza for a few days, when his breathing became so difficult as to alarm his family, and I was summoned in haste to see him.

I found him sitting in a chair, suffering most intense dyspnœa, expectorating frothy bloody water. Pulse very irregular, rapid and feeble, lips, face and fingers cyanotic and extremities as cold as those of a corpse.

With a lancet I freely scarified the skin in a half dozen places over the front and back of his chest, over which I applied tumblers, having first exhausted the air by burning cotton in them, and in this way drew a half pint or more of blood, at the same time putting his feet and hands into a hot mustard bath, and giving him two grains of carbonate of ammonia every fifteen minutes. After the cupping I ordered his chest covered front, sides and back with hot mustard and flaxseed meal poultices, and with the purpose of unloading the portal veins, and thus relieving the right breast, administered that much prized and perhaps much abused cathartic of our fathers, ten grains of calomel with fifteen of jalop, and left the old man with the feeling that I could not be charged with omissions in this case at any rate.

The next morning I was much gratified to find him entirely comfortable, and without any vestige of the alarming pulmonary œdema of the previous evening.

Was sent for by another physician to do a tracheotomy upon a little girl aged four years, dying with membranous croup. The child, who had been struggling with most intense dyspnœa for many hours, was thoroughly exhausted and very cyanotic, and when placed upon the table, pulse and respiration ceased. Thinking that the introduction of the tube into the trachea might resuscitate her, I proceeded with so much haste and nervousness, as to cut one of the superior thyroid veins, causing a profuse flow of black blood, when my patient at once began to breathe, the pulse to beat with more strength than for hours, and the purple hue faded out of lips and skin. The hæmorrhage was arrested, the trachea opened, the tube inserted, and the child fell off into a quiet sleep, but died two days later with capillary bronchitis.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

MARCH 8, 1886, the President, DR. F. W. DRAPER in the chair.

PULMONARY ŒDEMA RAPIDLY APPEARING AFTER THORACENTECIS.

DR. BOWDITCH reported a case that he had seen in consultation, and which was the second case of the kind that he had met with in practice.

The patient was a man who had had severe rheumatism seven months before, which had resulted in a diseased heart. There was little rubbing, but the area of cardiac dulness was increased, and there was some dyspnœa. Digestion was fair, counter-irritants were applied over the heart and gave some relief.

Fourteen days later Dr. Bowditch saw the patient again. In the meantime there had been a left-sided pleural effusion, which still existed, and for which tapping had been attempted but without getting any fluid. The physical signs were different from when the man was last seen by the speaker. Dulness extended backward from the left axillar line. The front was somewhat tympanitic. The heart was pushed up and to the right. Aegophony was heard, and also some râles in the back, but these last were probably transmitted. The speaker had urged another attempt at tapping, and owing to the patient's weak condition it was done while he was lying down, the needle being inserted between the seventh and eighth ribs. The discharge of serum was very free, and three pints were withdrawn. Before this quantity had been wholly removed the patient, who was sucking ice, coughed; but the needle was not immediately removed, as the operator believed that the cough was merely choking over the melted ice. As the cough continued the needle was removed.

DR. BOWDITCH does not mean to say that the cough had anything to do with the final result. Dyspnœa and death followed in less than forty-eight hours. Autopsy showed an expanded lung full of serum.

This is the second case of the sort that Dr. Bowditch has in three hundred and ninety-eight operations, and the other had recovered.

DR. E. H. BRADFORD read a paper on

THE CAUSES OF LATERAL CURVATURE.[1]

DR. HAVEN asked the reader if weight habitually carried on one arm and transmitted from the shoulder, had in his opinion that effect in causing curvature which had been ascribed to it.

DR. BRADFORD said that in that case the position would be faulty, and therefore would predispose to a lateral curvature if other conditions were present. It has even been supposed that the peculiar curvatures thus arising from different trades might be sufficiently distinct to admit of classification.

To other questions Dr. Bradford answered that rickets is not usually a cause of lateral curvature unless we assume the rickets of adolescence; for the reason that rickets is commonly over before the age when heavy enough weight is carried to cause curvature, the weight of the head in early childhood being slight, while lateral curvature rarely begins before the eighth or tenth years. A rickety patient either lies down or holds himself erect. He does not usually loll about.

DR. J. J. PUTNAM inquired if the paper covered all the causes of lateral curvature.

DR. BRADFORD said that he thought that these factors and these alone are efficient.

In answer to a question by Dr. Fitz, he said that the changes in the bone and cartilage are in his opinion nutritive changes secondary to position, which last is due to muscular weakness in most cases. Muscular weakness is not the only possible cause, as is shown by the reported case of two school-girls, twins, who occupied in common a narrow bench, and who leaned apart in order to gain room. Here lateral curvature of opposite sides followed, which evidently was not because of weakness but of long-continued position. The reader said in answer to questions, that it is perfectly possible theoretically to effect a cure in cases

[1] See page 241 of this Journal.

of marked osseous change; but that practically treatment for this object must be so rigid and so long continued that most surgeons are content with arresting the process. Where no osseous change as yet exists, muscular exercise may correct the deformity, but otherwise it will not do so. Preventive treatment consists in general care of the child's health, in addition to rest and strengthening of the weak muscles by proper exercise.

The amount of rest and the question of removal from school must be determined in individual cases. The speaker decides the question of overgrowth by comparing the weight, height, etc., with the average of American school children at the same age, as shown in Bowditch's tables. The strength of the muscles of the neck and of the back is tested and compared with what is expected at the given age or size.

DR. J. B. AYER reported a

CASE OF SCARLET FEVER (SECOND ATTACK) PRECEDED AND FOLLOWED BY A SCARLET RASH.

November 25th, he was called to see a boy, eleven years of age, whose body was covered with the characteristic scarlet fever rash, but there were no constitutional symptoms present. For three days the rash was well marked. There was no desquamation. He had had at five years old a typical attack of scarlet fever.

January 25th. He was surprised to find him again broken out with a similar rash, but more intense than before. At this time, however, he was ill; vomiting, fever, and congestion of the fauces were prominent, and desquamation of over three weeks' duration followed.

The house had hardly been disinfected when he was called, March 1st, to see the rash for the third time in fourteen weeks. Excepting a slight fever at the outset there had been no other constitutional symptoms with this attack. The rash lasted three days.

Now, the ninth day, his skin is rough in places, but the speaker finds no proof of fresh desquamation.

It is an interesting fact that the child's mother has passed through two severe attacks of scarlet fever.

In this connection Dr. Ayer mentioned the case of a girl ten years old, whom he isolated a year ago on suspicion of scarlet fever. He concluded at the end of five days, when the rash disappeared, that it had been of an erythematous character, as it had been situated principally in the flexures of the joints, and he dismissed the patient, but three days later she began vomiting and developed a typical attack of scarlet fever.

ENLARGED PROSTATE: DIFFICULT CATHETERIZATION: QUESTION OF CYSTOTOMY.

DR. GANNETT showed the enlarged prostate of a man of seventy-five, who had never been catheterized, and who died of another disease; but the specimen was interesting because of the great difficulty it would have presented to the introduction of any catheter but a soft one. One of the lateral lobes was much enlarged, bulging into the urethra and causing it to have a sharp lateral curve. Immediately beyond this was another sharp curve; this time in a vertical plane and caused by enlargement of the third lobe.

Dr. Gannett also showed the genito-urinary organs from a hospital patient of Dr. Bradford's. There was great hypertrophy of all the lobes of the prostate there contained diverticula, in some of which small calculi had lodged. There were old false passages and there was cystitis.

DR. BRADFORD said that owing to the great difficulty made by the false passages, there had been a question of immediate cystotomy, but that it was decided that as the patient was eighty years old, that immediate cystotomy was unjustifiable. The patient lived but three days, and considering the result it may be a question which would have been the better operation.

ANCHYLOSIS OF ELBOW: FRACTURE OF ELBOW: GUNSHOT WOUND OF CHEST.

DR. BRADFORD showed an anchylosed elbow that he had excised, and which was a good specimen of this deformity, as it follows caries.

He also showed a large number of splinters of bone of various sizes, broken off from an old woman's elbow, by falling upon it.

He also showed the temperature chart of a case of traumatic pneumonia from a gun-shot wound in the chest.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

H. L. BURRELL, M.D., SECRETARY.

MEETING February 1, 1886, DR. G. F. JELLY in the chair.

DR. T. M. ROTCH reported six cases which had been under his care:

(1) SPASMODIC ABDOMINAL CONTRACTIONS. (2) PARALYSIS OF ARM IN CONGENITAL SYPHILIS. (3) TWO CASES OF EMPYEMA; I. AT EIGHTEEN MONTHS, II. AT FOUR YEARS. (4) DOUBLE PLEURITIC EFFUSION AT THIRTEEN YEARS. (5) SIMULATED VESICAL AND RENAL CALCULUS AT TEN YEARS.[1]

DR. A. N. BLODGETT said that he had been particularly interested in the cases of empyema reported by Dr. Rotch and felt that these cases were often neglected by practitioners. He had recently had a case where he had operated and had been much pleased with the result. He had applied the mackintosh to get a "valve action," as described by Dr. Cabot sometime since, and had not been successful in getting the mackintosh to act as a perfect valve. He spoke of the difficulty of getting the tubes to stay in position and said that he had at last taken a section of a rubber catheter and had softened it by heat so that it stayed very well in position.

He had found that iodoform by its odor was irritating to the patient and to the friends, and mentioned the value of mixing iodoform with coumarin.

This mixture completely masks the odor of iodoform and has an odor not unlike vanilla, if one could think of vanilla in the presence of iodoform. Further, coumarin does not diminish the antiseptic action of the iodoform. In one of his cases he had, on opening the chest, a very offensive discharge, the cavity was irrigated with Labbaraque's solution, one to twelve, with the result of completely removing all offensiveness from the future "washings-out." The Labbaraque's solution had no solidifying effect upon the pus, as described by Dr. Rotch.

DR. A. H. NICHOLS related the case of a middle-aged woman, formerly an over-worked teacher, who for many years had manifested spasmodic contractions of the abdominal muscles similar to those described by

[1] See page 242 of this Journal.

the reader. This patient was by no means of a nervous temperament, for during this period she had sustained with fortitude and without an anæsthetic several minor surgical operations. These involuntary contractions though usually moderate were at times severe enough to convulse the whole body, and were then accompanied by a loud guttural sound as if the diaphragm was involved. These movements resembled the contractions of chorea in that they were aggravated by the presence of a stranger, and were uniformly suspended during sleep; but they had not exercised any appreciable effect in impairing her general health.

Dr. W. B. Hills said that the case reported by Dr. Rotch of "symptoms simulating renal and vesical calculus" was typical of a class of cases that occur which are a source of much anxiety to both patients and physicians. He felt that there was a great deal to learn regarding the uric-acid diathesis.

Not infrequently when he reported to a physician that there was a deposit of uric acid in the urine he was asked, Why is the uric acid there? and, What shall we do about it? An occasional deposit of uric acid in the urine is of no consequence, but when it is persistently present it certainly should be considered as endangering the patient to the formation of a calculus. It is generally known that the urates exist in the blood, and they may be deposited in the following places: *First*, in the tubules of the kidney where they may cause disturbance or may pass off in the form of gravel. *Second*, in the bladder where they may form a calculus. *Third*, outside of the body where it is of course of no importance.

There are certain conditions of the organism that seem to favor the formation of uric acid; namely, it is more common in winter than in summer, it recurs in chronic diseases of the respiratory organs, it occurs where there is an imperfect action of the skin, it follows attacks of gout and when the food is not properly assimilated. In children, Dr. Hills felt that it was due to some derangement of the system. The symptoms are pain in the bladder and pain in the back. Regarding treatment he considered that the rational way of treating the affection was to favor oxidation. No general prescription can be given which will be useful in every case. The physician must systematically interrogate the various functions of the body and correct the one that may be deranged. The patient should have plenty of fresh air, moderate exercise, a proper diet, and the function of the excretory organs should be set aright.

Medicinally the administration of the alkalies favor the solution of the urates, and the giving of large quantities of water is a useful adjunct.

It is interesting to know that the supervening of any intercurrent affection frequently causes the uric acid to disappear from the urine.

Dr. A. T. Cabot said that he was sorry to hear Dr. Minot speak slightingly of antiseptic treatment in empyema, for in his experience the aseptic conduct of the wound had the greatest influence upon the safety of the convalescence. Of twenty cases that he had operated upon in this manner, about one-half were in private practice, the other half in hospitals, and the success in the private cases had been much more gratifying than in those treated in hospital practice. This would seem to show that the septic influences encountered in hospital atmosphere and dressings did retard the process of cure. And this belief is still further strengthened by the fact that two of the hospital cases which did exceptionally well were ones in which Dr. Cabot did all of the dressings himself and brought in the dressing materials (gauze, etc.) from outside. One of these cases was that of a young man in whom the pus evacuated was of an exceedingly fetid character. The cavity was closed in twelve days, the tube was taken out and the tissues in which it had lain quickly healed.

The other patient was a young woman about twenty-eight years old, and in her case the tube was taken out on the seventeenth day, and the opening quickly closed.

As children do well by many different methods of operating, it is not easy to draw conclusions from their cases as to the efficacy of different plans of treatment. In adults, on the other hand, the case is different and a cure is far more difficult to obtain, yet the speaker could recall five cases of adults in which a complete cure was obtained within a month by the method of treatment which he advocated.

This is a record which he had not seen equalled in the reported statistics of any other method. In regard to the valvular action to be obtained by the proper application of the rubber cloth or mackintosh, he regarded it of the greatest importance in promoting the rapid expansion of the lung and closure of the cavity.

Any one without a moustache can easily test this by holding a piece of rubber cloth lightly over the mouth and forcibly breathing in and out while the nose is held.

In dressing the chest the mackintosh should entirely overlap the innermost dressing of gauze, and then the elastic dressings outside of it hold its edges applied to the skin and make a very perfect valve. Under this dressing properly applied, the lung is often fully expanded in from twenty-four to forty-eight hours. This of course only in cases of simple empyema where there is no consolidation of the lung and where it is not tied up by adhesions.

Suppose such a lung is released by the emptying of the cavity of pus; as it expands and the two surfaces of the pleura come together they quickly adhere. Now if the expansion is so favored that it takes place quickly and the lung is at once brought down to its normal position, it adheres there and the cavity is soon closed. Suppose, however, on the other hand, the lung only partly expands and so partially fills the pleural cavity. Here again it becomes adherent, but it becomes adherent in the wrong place and these adhesions afterwards make its further expansion difficult if not impossible, and the closure of the remaining cavity has to be effected by the collapse of the chest wall and displacement of neighboring viscera.

These considerations show the wisdom of any course which will favor the rapid expansion of the lung, and the proper intelligent application of the mackintosh will do much in this direction.

Dr. Blodgett said that his operation was strictly antiseptic and was kept aseptic throughout.

Regarding his failure to have the mackintosh act as a valve, perhaps he should have said, "that he failed to get that degree of valve action that he had hoped for."

Dr. Cabot said that if a lung was consolidated or had been perforated, of course the valve action of the mackintosh in assisting the expansion of the lung would be greatly impaired.

Dr. Rotch referring to the difficulty that Dr. Blodgett had met with in adjusting the mackintosh,

as recommended by Dr. Cabot, said that he also had failed to make it work satisfactorily, although he had employed it in both cases, but he had purposely avoided mentioning this, as he had come to the conclusion that the method was a good one, and that he himself was as yet not sufficiently skilful in his application of it to justify criticism.

He also remarked that he had been greatly aided in the antiseptic precautions taken in the second case, by Mr. Perkins, who assisted at the dressings.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

TWENTY-FIFTH ANNUAL MEETING, January 9, 1886, the President, DR. A. D. SINCLAIR, in the chair.

PROLAPSE OF THE FUNIS.

DR. RICHARDSON alluded to a case of twin labor at eight months and a half, complicated with prolapse of the cord. In this, as in most other cases, it was easy enough to replace the cord within the uterus: the difficulty in all such cases lies in carrying the funis sufficiently high, and keeping it there sufficiently long to enable the presenting part to occlude the superior strait, and thus prevent a second prolapse. In the case referred to, not having at hand any of the instrumental devices for replacing the cord, he made use of the following expedient:

An English gum-elastic catheter was softened by immersion in hot water, the stylet slightly withdrawn, and, by bending back the tip of the catheter, made to protrude from the eye. A loop of narrow tape about three inches long was then placed around the funis, and the two ends of the loop passed over the tip of the stylet, which was then slipped back through the eye into the tip of the catheter. The funis, being thus secured to the end of the catheter, was readily carried high up into the uterus: the catheter was allowed to remain in situ until the presenting part had occluded the brim; then the stylet was withdrawn, thus freeing the funis, and the catheter was taken away, leaving the loop of tape behind to escape after the birth of the child. In subsequent cases, this method had commended itself to him as safe and efficient: moreover, it did not require a special instrument for its performance.

DR. BLAKE said that he had tried various devices for replacing the cord, but had not usually been able to keep the cord in the uterus after he had replaced it there: he had usually, therefore, in such cases, delivered as soon as possible with forceps or by version.

DR. REYNOLDS said that in roomy pelves the cord could often be put in a position where it would escape pressure. He also alluded to the danger, in rapid deliveries, of catching a loop of cord between the forceps and the head, and thus destroying the child: the accident cannot always be avoided; but the possibility of its occurrence should be borne in mind.

POST-PARTUM GLYCOSURIA.

DR. MINOT reported the case of a healthy woman of nervous temperament, who was normally delivered of a healthy child, and whose convalescence progressed favorably for ten days. On the morning of the eleventh day, the mother awoke with a headache. The temperature was elevated one or two degrees: there was no chill, no pain, and no tenderness. The skin was hot, but not dry: the lochial discharge was normal. The specific gravity of the urine was 1030: there was a slight trace of albumen, and a large trace of sugar. The bowels had not moved on the day before, as they had regularly done previously. After the exhibition of purgatives the symptoms declined, and all went well the next day. The gravity of the urine was 1020, and the amount of sugar was about the same. After a few days it had nearly disappeared. Dr. Minot had never noticed the complication of glucosuria in the puerperal condition, and asked if other members of the Society had met with such cases. He would not have attached much importance to the occurrence, if the patient had not been of a nervous temperament.

DR. RICHARDSON said that sugar was often present in the urine during the establishment of lactation; and also at any time during lactation when there is any marked disturbance of that function.

SHOULD INFANTS BE NURSED AT NIGHT?

DR. REYNOLDS asked the opinion of members of the Society about the advisability of feeding young infants at night. An undisturbed night's rest is of great benefit to the nursing mother; but is it not cruel to compel the infant to go for eight hours, from evening to early morning, without nursing?

DR. T. M. ROTCH, present by invitation, thought it was injudicious to begin to train an infant to go without food at night during the first two months. During this time the infant's welfare is liable to be disturbed from other causes, and therefore he believed the feeding should be as regular at night as in the daytime.

DR. BOARDMAN believed that infants should sleep at night, as well as adults. If the mother has a sufficiently abundant supply of milk to satisfy the infant in the daytime, there is no reason why the child should be nursed after the mother's bedtime until morning. If the child is restless, it does not follow that it needs nourishment: oftentimes change of position or attention to the clothing and napkins will quiet the infant and cause it to go to sleep again. The difficulty of maintaining discipline is with the mothers, who are too apt to believe that a restless infant ought to be nursed, or who find the breast a more convenient way to quiet the child. He had succeeded in many cases in his practice in carrying out his views on this subject, and had never seen anything but good result.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

W. H. TAYLOR, M.D., RECORDING SECRETARY.

MEETING at the Rooms of the Boston Medical Library Association, February 3d, 1886.

The meeting was called to order at 12.05 P. M., by PRESIDENT WINSOR. Present, twenty-nine members. Records of the last meeting were read and approved.

The Secretary read a communication from Clark Bell, Esq., of the New York Medico-Legal Society, requesting the appointment of two members of this Society to act with him in preparing statistics concerning the insane, in conformity with the plan offered at the International Congress held at Antwerp, Belgium.

On motion of MEDICAL EXAMINER TOWER, the President was appointed one of a committee of two to communicate with Mr. Bell upon this subject. On motion

of Medical Examiner Draper, Medical Examiner Ira Russell, of Winchendon, was appointed as the second member of this committee.

Medical Examiner Paddock read a paper upon

THE DUNBAR CASE.

The case was of interest from the fact that it was difficult to determine from post-mortem appearances alone, whether it was a suicide or homicide. The essayist, in a careful and interesting paper, gave his reasons for favoring the view of suicide.

Medical Examiner Fish read a paper upon the same case, giving a very ingenious explanation of the method which, in his opinion, the suicide employed to effect his purpose.

The papers were discussed by members Holmes, Bronson, Hurd, Adams, Paddock, Fish, Tower, Winsor, Harris, and Abbott.

On motion of Medical Examiner Holt, Dr. J. L. Sullivan, of Malden, Ex-Medical Examiner, was made a regular member of this Society by a unanimous vote.

Medical Examiner Harris made a verbal report of a case of resuscitation of an infant nine or ten days old, who was exposed to the cold and wet of January 31st and February 1st for twenty-eight hours without nourishment. Adjourned.

Recent Literature.

A Reference Handbook of the Medical Sciences, Embracing the entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Illustrated by Chromo-Lithographs and fine Wood Engravings. Edited by Albert H. Buck, M.D., New York City. Volume I. New York: William Wood & Co. 1885.

The first volume of 808 pages, imperial octavo, of the eight which it is thought will be necessary to cover the field as proposed, is very creditable both to the publishers and to the editor. If the other seven volumes reach the same standard the work will be one of unusual value for consultation "on all the important topics belonging to the broad domain of medicine."

In deciding upon the character and scope of the handbook, the editor has to choose between two courses: "either to retain a reasonably full list of topics and give to each its proper share of space, or to curtail the list, and so gain enough space for a fairly satisfactory and thorough treatment of at least the more important subjects." The former plan, the one generally pursued in books of reference which can with any propriety be called handbooks, favors brief and unsatisfactory articles; the latter plan necessitates the omission of some of the less important topics. The latter evil seemed to the editor, and we think, justly the less of the two; accordingly he has aimed at presenting to the profession a medical encyclopædia whose articles shall convey a certain fullness, rather than one which covers — though superficially — every possible title in medicine and the many collateral sciences. The larger portion of the space is devoted to practical subjects — the diagnosis and treatment of disease — but such collateral departments of medical science as botany, climatology, embryology, physiology, physiological and pathological chemistry, applied anatomy, medical jurisprudence, military and naval surgery have been by no means neglected.

Each article is signed with the writer's name. Of course, when coming from so many different writers — there being no less than ninety contributors to this first volume — the articles are of varying degrees of merit. In general, however, our examination of the volume, which has been far from a hasty one, leads us to the conclusion that the writers, even for the less important subjects, have been carefully selected, and that they have done their work well. Without mentioning any individual names, we do not hesitate to say that the treatment of some of the topics could not easily be improved upon.

The illustrations have been generously and in most cases judiciously supplied. The wood-cuts are well made and really illustrate instead of confusing the text; the volume contains in addition four handsome chromo-lithographic plates. The paper is good and the type is clear.

The expense of publishing such a work is necessarily very great, entirely apart from any remuneration offered to the writers of articles: the cost to the subscriber must also be large, but the purchaser has the consolation that he is really getting something for his outlay. We understand that the second volume will appear very shortly.

The Essentials of Physical Diagnosis of Thoracic Diseases. By E. Darwin Hudson, Jr., A.M., M.D. New York. 1885. pp. 63.

The title-page tells us that this manual was prepared for the use of the physicians in the class of general medicine and diseases of the chest of the New York Polyclinic. The methods of no two teachers are precisely the same in all respects, and sometimes differ widely in detail; a teacher is seldom, consequently, quite contented with his text-book unless he has written it himself, and it may be presumed that this fact has something to do with the appearance of this new claim on the attention of those studying physical diagnosis.

There is one special difficulty the medical student must constantly face, a difficulty unavoidable in a measure, because dependent on the progressive nature of our science, but so real, that instructors should never lose sight of it, striving to lessen it by every means in their power. We refer to medical terminology, which is so confusing in this relatively small subject of physical diagnosis, that a Committee was appointed at the London International Medical Congress to propose a uniform nomenclature. The Chairman of the Committee, Dr. Flint, than whom, certainly, no one is more fit, reported to the American Medical Association at the New Orleans meeting, two lists of terms, one his own, the other that of the English members of the Committee.

These two lists are very nearly identical, and either of them is, in our opinion, preferable to the classification of Walshe, whom Dr. Hudson follows in the main. Walshe thought that his classification could not be simplified without a loss in accuracy, but most authorities of the present day think otherwise. No American has done so much for physical diagnosis in thoracic disease as Flint; his teachings have extended throughout the land, and have been influential in England and on the Continent, and we fail to see the advantage of departing materially from his terminology, which is sensible, simple, and complete.

Hudson follows Loomis in the error — as our senses tells us — that tympanitic resonance is lower in pitch than vesicular. "Cracked pot or cracked metal quality is an air-impulse sound — air in a cavity rushing against its walls. Over trachea and large bronchial tubes, the percussion-sound is tubular. . . . the pitch is low, not hollow nor tympanitic, and the duration is long and ringing." What a hollow or tympanitic pitch, or a ringing duration may be, we do not know. Another example of want of care, is the use of "sputa" as if it were the nominative singular — "the sputa is:" this we note twice.

Cardiac hypertrophy is defined as "enlargement of the heart as a whole, or of the walls of any one of its cavities," a definition which does not clearly exclude dilatation. The prognosis of hypertrophy is said to be bad if that condition associated with dilatation, a statement far too general and very misleading. Not a word is said as to the bearing of enlargement of the heart on the differential diagnosis between organic disease and functional disturbance.

We have thus sought out some of the details which strike us as open to criticism; it only remains to add that the proof-reading leaves much to be desired.

A Manual on Animal Vaccination, Preceded by Considerations on Vaccination in General. By Dr. E. WARLOMONT, Founder of the State Vaccinal Institute of Belgium, etc. Translated by ARTHUR J. HARRIES, M.D. pp. 168. London. 1885.

This excellent translation comprises mainly, the fifth and sixth chapters of Dr. Warlomont's valuable treatise entitled, "*Traité de la Vaccine et de la Vaccination Humaine et Animale.*"

The author has added a note from Pasteur, which contains the following just comments on the character of the work:

"From one end to the other, your treatise is excellent for its clearness, for the perfect knowledge of the subject displayed, and for the place which you so judiciously give in it to modern discoveries, and to the relations which they hold to the questions of small-pox and vaccination, each of such great general and scientific interest."

The first portion of the book is devoted to the modes of origin of vaccine lymph. The celebrated remark of Depaul is quoted: "There is no vaccine-virus; vaccine is nothing but modified small-pox attenuated in its passage through the system of the horse or of the cow," and the author sums up the question as follows:

"We are compelled for the present, and we are sorry for it, to consider the theory of unicity as simply a hypothesis. A respectable hypothesis, however, for there is no other, that gives so well, a key to the complex problem of which we have been seeking the solution." This is more than Dr. Warlomont was wont to admit in his earlier publications.

The directions as to arm to arm vaccination, the choice of vesicles, and the preservation of vaccine lymph, are admirable. American authorities will be pleased to notice the prominence which this distinguished authority gives to ivory points, as employed for the storage of lymph.

The author alludes to the putrefactive changes and the mouldy smell to which the contents of capillary tubes are liable. Any competent microscopist who will examine the contents of a capillary tube which has been filled more than forty-eight hours, will find abundant reason to condemn their use for the purpose of vaccination.

In the chapter on animal vaccination, its advantages are clearly set forth. These are, mainly, the immunity from vaccinal syphilis, and the relative paucity of humanized virus. In support of the theory of vaccinal syphilis, the translator also judiciously appends a note containing the results of Dr. Cory's well-known experiments upon himself.

In regard to a third reason for employing animal vaccination, the degeneration of humanized vaccine, the author concludes: "It is not the vaccine that degenerates, but the stocks, that use, or abuse it." The remarks on the technics of animal vaccination are of special interest to propagators of virus.

Certain usages advised by the author are open to objection. He recommends the employment of mucilage of gum-arabic as a coating for the protection of lymph upon points, a measure of doubtful utility, for two reasons: its liability to employment as an adulterant or substitute, and also its comparative insolubility.

Vaccine in pulp, either with or without glycerine, as well as any other moist methods of preservation, like the cones once employed by certain American producers, are liable to serious objections.

The question of the inoculability of tubercle is carefully discussed, its possibility having been urged in objection to animal vaccination, and while such possibility is admitted, its inoculability by *superficial* insertion of the bacilli (the common method employed in vaccination), is shown to be impossible. The following sentence, inserted in the English edition, commends itself to all American producers of vaccine lymph. A vaccine propagator who would resort to the careful methods therein proposed, and which is said to be practised at the Belgian Vaccinal Institute, would be worthy of public commendation and confidence:

"There is a method of placing beyond suspicion and any possible danger the preparations of animal vaccine furnished to the medical public, which consists in only delivering it to them after the animal from which it has been taken, has been proved by autopsy to be perfectly healthy."

The Temperance Teachings of Science. Adapted to the Use of Teachers and Pupils in the Public Schools. By A. B. PALMER, M.D., LL.D. Boston: D. C. Heath & Co., Publishers. 1886.

This book is a safe hand-book for the purposes for which it was designed; and teachers who wish to give oral instruction upon the subject of the alcohol habit will find it useful. The author employs the term temperance in its popular rather than its actual sense; the book being devoted to the subject of alcohol to the exclusion of other harmful narcotics and stimulants.

The book is divided into twelve chapters, in which the effect of alcohol upon the various organs of the body appears to be correctly and briefly stated.

— Vogel relates the following in his "Diseases of Children": "I once treated an American lady, who still suckled her son, who was *two and a half years old*, till one morning, when the strongly-developed, robust child was called to be nursed, he very kindly replied: 'I thank you, dear mamma, the nursing is too tedious for me.'" —*Gaillard's Medical Journal.*

Medical and Surgical Journal.

THURSDAY, MARCH 18, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO. *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

THE SURGICAL TREATMENT OF PERITYPHLITIS.

MEDICAL practitioners are, we believe, fully agreed as to the propriety of surgical interference in those cases of perityphlitis where suppuration has taken place in the cellular tissue about the appendix. The diagnosis of a perityphlitis is not ordinarily difficult, but to recognize the exact moment when expectancy should yield to action and the knife should make a passage for the pus already formed is certainly a matter of difficulty. To wait for fluctuation is to expose the patient to all the dangers of perforation and peritonitis, and the physician himself to the accusation of dilatoriness and timidity where the only safety lies in bold and immediate action. To operate before the formation of pus is certain to expose the patient to the dangers of an operation of some gravity for a disease which often recovers without such interference.

The indications can hardly be called definite. Everything depends upon an exact diagnosis, but the means of making an exact diagnosis are not perfectly understood, and he who adds to our means of definitely distinguishing the condition and fixing the time of operation will deserve the thanks of his colleagues.

Dr. Wm. T. Bull, of New York, has recently reported a case of perityphlitic abscess in which an incision was made at an earlier moment than in any case previously reported.

The patient, a gentleman thirty years of age was suffering, when first seen, from very severe pain in the right iliac fossa radiating down the thigh, with a temperature of 103° and pulse of 120. The abdomen was normal on examination except that in the right iliac region there was dulness and exquisite tenderness (so that percussion was very unsatisfactory), and a sense of fulness or increased resistance on palpation. These were the only signs of an exudation. He had been in bed but forty-eight hours, although for ten days previously he had experienced a steady dull pain in the inguinal region, with occasional paroxysms which were more severe. He was constipated for a week during this time, but the bowels moved naturally three days before I saw him. His symptoms were not sufficiently acute to deter him from a week's railroad travel, and on his return they presented the features mentioned above.

Dr. Kinnicutt, who was the medical attendant, had suggested exploration, and it was done at once. The needle, thrust to a depth of three inches directly backward into the iliac fossa, produced no pus; nor was any obtained when it was thrust in front of and behind this site. A longer needle was then pushed from a point behind and above the anterior superior spine, toward the middle of the fossa, a depth of four inches, and through it the syringe drew some very offensive and bloody pus. The incision was made a few hours later, under ether, above and to the outer side of the middle of Poupart's ligament. The tranversalis fascia was thickened and grayish in color, the muscular layers absolutely healthy in appearance. An incision through the fascia evacuated about an ounce of pus, very dark from blood, and of characteristic odor. No foreign body escaped, and as the time of operation was so early I did not deem it wise to thrust the finger into the abscess cavity; but an elastic bougie showed that it extended from the centre of the incision about two inches toward the symphysis and three or four toward the lumbar region. The pain and fever disappeared next day. The cavity reduced to a sinus four inches deep was slow in healing. At the end of six weeks a foreign body was detected in it at a depth of three inches and removed with dressing forceps. It proved to be a calculus, doubtless formed in the appendix.

The sinus closed in a week. The concretion is as large as a white bean, calcareous in composition, the salts being arranged in concentric laminæ, and with no foreign body as a nucleus.

It is to the comments of the author that we wish to draw attention, and especially to his remarks upon the use of the aspirator in diagnosis.

"In this instance," says Dr. Bull, "the operation was performed at an earlier moment than in any case that I have seen recorded, and I think that the thorough exploration with the needle and hypodermic syringe was the chief factor in bringing it about. I have several times withdrawn pus from the iliac fossa, through a puncture made from the lumbar region downward and forward toward the middle of the iliac fossa, when punctures directly into the fossa or the tumor occupying it were fruitless. A good-sized needle is indispensable (No. 3 or 4 of the French scale for urethral instruments) and a "tight" syringe. These punctures are "harmless" (we trust we shall escape the charge of too great carefulness in the use of words if we prefer to say these punctures are so nearly harmless, that the possible danger should be disregarded when anything so important as a positive diagnosis is to be gained), "and should be made into the lumbar region, as well as into the iliac fossa. We are familiar with their value as a means of diagnosis, but I would like to emphasize

the advantage of making such thorough explorations as I have described.

"But I desire to claim something more for the needle, and that is, that it is the only trustworthy means of ascertaining the presence of pus. Both the general symptoms and the local conditions mislead us in this respect. There are patients who are attacked with high fever, severe pain, chill, and even sweating, whose inflammation undergoes resolution; and there are others in whom the abscess reaches great proportions with trifling disturbance.

"The necessity of opening the abscess early — and long before fluctuation has occurred — has been insisted on with justice by a number of writers. I have but one suggestion to make on this point, and that is, in determining the *time* to operate, the *duration* of the illness should play a rôle subordinate to that of the results of exploration with the needle. It is certainly undesirable to operate too early, when the pus may not have formed, or the inflammation be going on to absorption. It is equally undesirable to defer the incision, and subject the patient to the risks of an unfavorable course on the part of the pus. A sort of 'time allowance' has been fixed by some surgeons. Gouley fixes the seventh or eighth day as the proper time for incision; Weber 'not beyond the ninth or tenth'; Sands, from the twelfth to the eighteenth day. From this discrepancy, it is obvious that the 'time allowance' is of no use, and that it will be far wiser to be guided by the evidence afforded by *needle exploration*."

This case of Dr. Bull's draws attention to an anatomical detail in the diagnosis of pericæcal abscess which is not sufficiently insisted upon: that is, the formation of the pus beneath the transversalis fascia. To wait for fluctuation is to wait until the fascia has been perforated, and the tendency of the abscess to spread beneath the fascia before seeking an external outlet, is well illustrated in this case by the distance to which the bougie penetrated: the cavity held but an ounce, but extended some five or six inches. Some remarks of Professor Pepper describe very well the condition of affairs.

"It is not too much to say, that the unjustifiable delay permitted in many cases of typhlitis, whilst hoping, day after day, for the more definite detection of suppuration, is the direct cause of many avoidable deaths. It is true that ordinarily, the approach of suppuration will be announced by a change in the constitutional symptoms, by the occurrence of rigors, followed by sweats, febrile movement of a remittent or hectic type, and increased acceleration of pulse. But, on the other hand, it is certain that after an abscess has already formed, the general symptoms may merely indicate increasing gravity of the case, without presenting the above indications of suppuration. So, also, it must be borne in mind, that the existence of a pericæcal abscess may be unattended with the local appearances which usually accompany suppuration. In many cases where a considerable amount of pus has been found, the cæcal tumor, immediately before operation, was hard, absolutely without fluctuation on palpation, and resonant on percussion. This may be due to the fact that at times, the pus is chiefly confined behind the thickened and inflamed cæcum, which is pressed forward against the abdominal wall; or, again, that the pus, either collected to the outside, or in front of the cæcum, is so compressed by the tense transversalis fascia and abdominal muscles, that fluctuation cannot be detected on percussing over the abscess until an incision has been carried down to, or through this fascia."

CREMATION, A CONSERVATIVE VIEW.

IN the history of every alleged reform there are fortunately always to be found men of conservative tendencies, who put on the brakes long enough to give an opportunity for a calm and quiet reconsideration of the subject. To move a reconsideration does not jeopardize a really needed reform, and it enables the public to revise their beliefs which are perhaps in danger of becoming unduly ardent under the exhilarating effect of too rapid and uninterrupted "progress."

At a recent meeting of the New York Society of Medical Jurisprudence and State Medicine, Dr. Frank H. Hamilton read a paper entitled "Cremation not Required as a Sanitary Measure." The subject had been brought up by the introduction of a resolution by Dr. W. M. McLaury that the Society request the Legislature to pass an act making cremation compulsory in the case of paupers and those dying of contagious or infectious diseases. Dr. Hamilton said that the danger to life and health from burial four to six feet under the soil, as practised in this country, had been greatly exaggerated, if, indeed, it could be said to exist at all. He cited the testimony of the eminent French authorities, Duchatelet, Dubois, Dupuytren and Boyer, who all concurred in the opinion that it was an error to suppose that the air in the neighborhood of graveyards or dissecting-rooms was contaminated by emanations from dead bodies. There was no more danger arising from the presence of human remains than from those of other animals, and if incineration was needed by the human race for protection against decaying animal matter and the germs of disease, nothing short of the cremation of the whole world would avail. He contended that the emanations from dead bodies, though offensive, were not, as a rule, dangerous. The trouble with those who urged cremation as the only proper disposition of the dead was, that they never took their examples of the evils of earth-burial from their own country. They went to Italy, and Egypt, and Turkey, and to all sorts of places; but they hesitated to meet their opponents on their own soil. After dwelling on the undeniable fact that cremation would often destroy traces of crime and make detection impossible, Dr. Hamilton said: "In this country there is a strong public feeling opposed to even voluntary cremation. The same is true of civilized nations in all parts of the world, and

especially among those calling themselves Christian. This may be only due to sentiment, but no true friend of the human race, Christian or infidel, would wantonly destroy that sentiment. If any one desires to be cremated, there exists no valid reason why he should not be; but I argue that it is totally unnecessary for any sanitary reasons, and therefore that there is no need that cremation should be enforced by legal enactment, or that it should be even urged upon a reluctant public.

DR. AUSTIN FLINT.

This eminent physician and teacher died suddenly at his home in New York, on Saturday last. Of an illustrious medical ancestry, the occupant during the last forty years of professional chairs in no less than six different cities of the union, the author of a standard work on practice which has passed through several editions, the recipient of the highest honors in the profession, his death will be felt throughout the medical world. We defer to a future time a more extended and fitting notice of his fruitful life.

MEDICAL NOTES.

— Mr. Lawson Tait has been elected President of the British Gynæcological Society.

— Apropos of the recent exceptionally cold weather, it is interesting to learn that the coldest weather ever recorded on the globe was that experienced in January, 1885, in the expedition under Dr. Burrage, to the new Siberian Islands, and reported to the St. Petersburgh Academy of Sciences at the annual meeting on January 10th last. The mean temperature of January, 1885, was −52.7° C. (−62.9° F.), and the minimum −68° C. (−90.4° F.).

— A case is recorded in the *British Medical Journal*, (December, 1885, page 1104,) of a female, aged forty years, who was admitted into the Philadelphia Hospital in a delirious typhoid condition. The abdominal cavity was filled with a large tumor, which extended to the ribs. It was globular, movable, tense, and distinctly fluctuating. For five or six weeks, the urine had dribbled away constantly. The author diagnosticated a distended bladder, and introduced a catheter; by this means, during the next twenty-four hours, he drew off 464 ounces of urine. Next day, a partially decomposed four-month's fœtus was passed. For the next three weeks, the patient was unable to pass urine naturally, but the bladder gradually regained its tone, and in three months the patient was cured.

— For engaging in the practice of medicine in China, no license is required, says the *Medical Record*, but the lot of the unsuccessful physician is not one to be envied. The following is the two hundred and ninety-seventh section of the penal code, which deals with these unlucky practitioners: "Whenever an unskilful physician, in administering medicines or using the acupuncture needle, proceeds contrary to the established forms, and thereby causes the death of the patient, the magistrate shall call in other physicians to examine the medicines or the wound. If it appear that the injury done was unintentional, the practitioner shall then be treated according to the statute for accidental homicides, and shall not be allowed any longer to practise medicine. But if he have designedly departed from the established forms, and have practised deceit in his attempts to cure the malady, in order to gain property, then, according to its amount, he shall be treated as a thief; and if death shall ensue from his malpractice, then, for having thus used medicine with intent to kill, he shall be beheaded."

— We are not in the habit of going to the *London Truth* for medical hints, but its quotations are, perhaps, reliable, and it certainly has a lively way of putting things. It says: "According to the *United Service Gazette*, a new use has been discovered for the musical instrument of torture called the bagpipes. Last year a Spanish soldier was brought to the Military Hospital at Havana in a state of catalepsy, and for fifteen months he showed no signs of improving health. At last, the doctors ordered the bagpipes to be played near his bed, whereupon the man promptly recovered consciousness, and was soon able to articulate. The first words were not couched in the form of a blessing; but there may be yet a great future for the bagpipes in medical science. Their music may be strongly recommended to persons suffering from nervous or hysterical disorders, and generally speaking, to maladies imaginaires of every description. Whether the disease or the remedy is the worst, must be left to the judgment of the invalids themselves."

NEW YORK.

— The Council of the University of Buffalo have decided to establish a college of pharmacy in connection with the Medical School, and Prof. R. A. Witthaus has been elected head of the Faculty.

— The seven dogs bitten by the supposed rabid dog which bit the six Newark children about the first of December last, were released from pound March 2d, no symptom of rabies having developed in any one of them during the three months of their confinement.

— At a meeting of the Academy of Medicine held March 4th, Dr. D. B. St. John Roosa read a paper on "Limitations in the Value of Glasses for the Improvement of Vision and the Relief of Disease," the main object of which was to show that the tendency had of late been to attribute altogether too many diseases, both reflex and organic, to troubles of the eye. Afterwards, Dr. Henry G. Piffard exhibited a new electric light, the advantages of which were: a lamp of fair constancy and a portable battery (six cells), at moderate expense. The apparatus was made by the Galvano-Faradic Company, of Fourth Avenue, New York.

— Dr. Ludwig R. Sattler, the veterinary, who was the last of the Newark patients who went to Paris to

be inoculated for rabies by Pasteur, returned on the Eider, which arrived February 28th. He states that the report published in the newspapers that M. Pasteur refused to treat him because he could not produce satisfactory evidence of having been bitten by a rabid dog was false. As soon as he arrived in Paris, he went to the laboratory, where he was courteously received and allowed to inspect the processes of preparing the virus for use in the human subject. He was inoculated nine times in all.

— The fifth annual meeting of the New York Medical Missionary Society was held at the Broadway Tabernacle, March 2d. Dr. C. R. Agnew presiding. Dr. George D. Dowkoutt, Medical Superintendent of the Society, gave an account of its work during the past year, and addresses were made by several medical missionaries, as well as by Dr. Agnew. There are now nine young men in course of training, under the auspices of the Home Institute of the Society, which has for its object the maintenance of students preparing for medical missionary work, and some fifty applicants have been refused for lack of the funds necessary to pay for their education. Mr. Cornelius Vanderbilt has given $600, and his brother George, $300, for the expenses of the current year.

— A striking commentary on the report of State Engineer Gardiner, in regard to the sewerage and general sanitary condition of the new capitol building at Albany, which was recently presented to the State Board of Health, was afforded on March 11th, when a violent explosion in front of the building caused no little excitement among its occupants. It was supposed at first that dynamiters had been at work, but an examination of the premises showed that the detonation and upheaval were due to an explosion of sewer-gas in the large receiving basins below the building; heavy stones three and five inches thick, which covered the basins, being shattered into a thousand pieces and hurled through the air. The accident is said to have been the direct result of the imperfect system of sewerage and ventilation, to which the State Board of Health has called the attention of the Legislature.

— Dr. Charles H. Phelps has been nominated by Governor Hill for the position of Health Officer of the Port of New York, and the appointment is generally considered a most excellent one. Dr. Phelps is a well-known surgeon, who has filled with ability a number of responsible positions, and is at present an attending surgeon to Bellevue and St. Vincent's Hospitals, as well as President of the Medical Board of Bellevue and of the Board of Police Surgeons, of which he has been a member for a considerable time. Although a Democrat in politics, there is little doubt that Dr. Phelps will be confirmed by the State Senate in which there is a Republican majority. The Governor has also appointed one of the Commissioners of Quarantine, Dr. John H. Douglass, well known by his connection with the case of Gen. Grant, the other two commissioners appointed being prominent and highly-respected business men, Messrs. Marshall B. Blake and Charles S. Higgins.

— The State Charities Aid Association have recently had introduced into the Legislature a bill providing for the establishment of municipal lodging-houses, on the plan of the Wayfarers' Lodge opened by the Overseers of the Poor, in coöperation with the Police Department, which has been in successful operation in Boston since 1879. This act authorizes the Commissioners of Charities and Correction to hire or purchase the necessary buildings, subject to the approval of the Board of Estimate and Apportionment. The houses once established, it will be unlawful to shelter any persons but women, children or aged or infirm men in police stations. The lodging-houses will receive all other applicants, subject to proper conditions, and provide them with meals and a night's lodging, in return for which they will be expected to perform a reasonable amount of labor in the morning; and in case any lodger refuses to do this he will be subject to prosecution as a vagrant. Each applicant will also be compelled to take a bath and have his clothes disinfected. It is estimated that four lodging-houses will be required in all; but provision has been made in the bill for the experimental opening of a single one. As there are over two hundred thousand lodgings given in the city's police stations each year, two-thirds of the lodgers being almost constant in their applications, it is believed by its promoters that the adoption of the proposed plan will effect much good in New York, especially in the reduction of the number of professional tramps.

— Dr. S. Oakley Vanderpoel, of New York, died March 12th, at the Arlington Hotel, Washington, where he had stopped for a week on his way South. He came of a distinguished family, and was born February 22, 1824, at Kinderhook, Columbia County, N. Y., where his father, who was also a physician, carried on an extensive practice. He was graduated from the Jefferson Medical College, Philadelphia, in 1845, and in 1847 he went to Europe, where he remained till 1850, when he returned to this country and settled in Albany. He was appointed by Governor King Surgeon-General of the State in 1857, and was appointed again to the same position by Governor Morgan in 1861, when the duties of the office were extremely onerous and exacting. He served in this capacity with distinguished ability throughout the war, winning the public thanks of the Governor and the Legislature, and then once more returned to private practice. In 1860, he was chosen President of the Albany County Medical Society; in 1867, Professor of General Pathology and Clinical Medicine in the Albany Medical College; and in 1870, President of the New York State Medical Society. From 1872 to 1880, he filled the position of Health Officer of the Port of New York in the most admirable manner, during which time he lectured on hygiene at the College of Physicians and Surgeons, New York, and (in 1876), was appointed

to the Chair of Theory and Practice in the Albany Medical College. After his term as Health Officer, he returned to Albany for a year; but in 1881, came back to New York and engaged in private practice. In 1883, he was appointed Professor of Public Hygiene in the Medical Department of the University of the City of New York; and in 1884, received the degree of LL. D. from that institution. Dr. Vanderpoel was for a long time prominent in the directorate of the St. Nicholas Society, at whose gatherings his genial presence was always most highly esteemed. Personally, he was a man of great force of character, and his warm heart and kindly disposition won him hosts of staunch and devoted friends. Of his three sons, two are practising physicians in New York.

Miscellany.

A SECOND FLORENCE NIGHTINGALE.

The great assistance rendered to Senator Hawley in his official work by his late wife has been generally remarked upon since her death, but there was an interesting chapter in her life in connection with hospital service during the late war, which is perhaps not so well known, and which illustrates a strong and remarkable character. We make the following extracts from an obituary notice in the *Hartford Courant*:

In the fall of 1862, she joined her husband, then Colonel Hawley, of the Seventh Regiment, at Beaufort, S. C. From this time to the close of the war, she remained in active service as a hospital visitor. Many a soldier now living will forever bless her memory, and the last hours of many were consoled by her sweet ministrations. She devoted such time as her health would permit to the work at Fernandina, St. Helena, Hilton Head, and finally, in charge of a ward in Armory-square Hospital, in Washington, a position to try the nerve and exhaust the vitality of the strongest nature. Mrs. Hawley reached this hospital the morning after the wounded began to arrive from the battles of the Wilderness. Her ward was one of the largest, containing at one time ninety-seven patients, and to add to its horror, there was no separate operating room. In one day during that terrible April, forty-eight patients died. The hospital, which was designed for 900 patients, was at this time compelled to receive and care for 1400.

Surrounded by such scenes, Mrs. Hawley lived in the hospital in charge of the ward assigned her for four long months — months of the severest labor, taxing her utmost strength, and drawing upon her deepest sympathies. In September her health failed, and she was obliged to relinquish the charge, returning, however, in November, and remaining until March, 1865.

After the capture of Wilmington, N. C., General Hawley was assigned to the command of a department with headquarters at that city. Here Mrs. Hawley joined him, and here she had a new experience of the horrors of war, in the reception of nine thousand Union prisoners from Andersonville and Florence. The city was in a filthy condition, fever broke out, prostrating hundreds, and the deaths were by the score. The chief of the medical staff died; of five professional lady nurses from the North, three sickened and two died; and among the detailed soldier nurses, the fatality was worse than in a battle. Mrs. Hawley exerted herself to the utmost to afford relief. She organized the women who volunteered to help, superintended the making of garments, visited the hospitals, and shunned no danger.

TWO CASES OF NEPHRITIS VARICELLOSA.

Nephritis is well known as a sequela of scarlatina, and occasionally of measles, but it is only within the last year or two that it has been observed to follow varicella, and very few cases have been as yet recorded. These two cases were observed at the Children's Hospital at Buda-Pesth, by Dr. Högyes, and are summarized in the *Edinburgh Medical Journal* from the *Jahrbuch der Kinderheilk*, Band xxiii, Heft 3, 1805. Case I, a boy, two and a half years of age, was admitted to the hospital for eczema of eyelids, on 14th October, 1884. On the 25th, he had a mild attack of varicella, contracted from another child in the hospital. On the 15th November, his face was observed to be puffy, and his urine was found to be scanty, and to contain albumen. He had a severe attack of nephritis, and died in three days. Post-mortem showed parenchymatous nephritis, and œdema of lungs. Case II, a girl of seven years, came into hospital with varicella on 28th October; a moderately severe attack. On the 21st November, she was observed to have face and feet swollen, and the urine was found to contain albumen. She had a short, but sharp attack of nephritis, but recovered, and was well by the 12th of December. She had suffered from no other disease, and the nephritis could only be referred to the varicella. The first symptoms of the kidney disorder appeared in each case from the nineteenth to twenty-first day after the first appearance of the exanthema.

UNPLEASANT EFFECTS FOLLOWING ANTIPYRINE.

Dr. W. Graham reports in the *Canada Lancet*, a case in which very unpleasant results followed the administration of antipyrine. On the 7th of October he was called to Mrs. B., aged forty-five, a patient in the fourth week of typhoid, whom he had been attending, and considered convalescent. Her temperature was 103.6°, pulse 120, respiration 30; fine crepitation throughout the lower portion of both lungs. He thought antipyrine the best selection as an antipyretic, judging that it would produce less depression than either quinine or salicylate of soda. He happened to have with him just one drachm, and divided it into five equal powders of twelve grains each, of which he ordered one every three hours. Next morning early, a messenger was sent with the unwelcome news that the patient was dying. On his arrival, he found her in a state of severe collapse. Cold perspiration stood in drops over her face and parts of her body, cold hands and feet, temperature, 95°; pulse feeble and flickering; impossible to count it. He was, indeed, alarmed, and expected to lose his patient. He immediately gave her ammon. carb. and digitalis, with whiskey at short intervals, and applied artificial heat around the body, and was very much pleased to find that this treatment

counteracted the unpleasant symptoms, and she ultimately recovered. Two or three days afterwards, her daughter drew his attention to a patch of purpuric maculæ about the size of the palm of the hand, on the back, just below the seventh cervical vertebra. This was, no doubt, the characteristic eruption that results from the use of antipyrine, but it was not observed on any other part of the body.

A CASE OF RETRACTION OF THE PENIS.

WE find in the *London Medical Record* (February 15), the following remarkable case which is recorded in the *Vratch*, No. 26, 1885, page 423, by Dr. A. A. Ivanoff, of Büzülük, Samara Government. A strongly built, generally healthy, married peasant, aged twenty-three, came to a local hospital, evidently laboring under some mental trouble, and stated that "something had broked down below" with him. On stripping the patient a string came to light, one end of which encircled the retroglandular sulcus of the penis, while another end was fastened round the lower part of the left thigh, the member being thus kept down in a tightly stretched state. The patient did not allow the author to touch the arrangement, and himself untied the femoral end of the string. On gradual relaxation of the latter, the penis slowly retracted, and ultimately disappeared altogether under the pubic arch, leaving only a navel-like depression. The part could be got back only by traction on the string. According to the patient's narrative, everything had been in due order up to five days previously, when having got up to micturate on a dark night, he was utterly frightened at being unable to find any trace of his penis. Having managed somehow to pass urine, he, after prolonged manipulations, was able at last to get it back, and to retain in the way mentioned. Except slight perineal pain, no other symptoms, and no possible cause whatever for the retraction could be detected. To allay the pain and the patient's distress, bromide of potassium, in ten-grain doses every three hours, was given. On the next day the penis remained unretracted for an hour or more. Six days later, retraction disappeared, and did not return. Dr. Ivanoff has not been able to find any other similar instance in literature.

A MODE OF CONCEALING THE TASTE OF QUININE.

The *Medical and Surgical Reporter* (Feb. 27) mentions editorially, a new method of masking the bitter taste of this drug, which was accidentally discovered by Professor Hugo Engel. He had been in the habit of prescribing in the moist stage of bronchitis, equal parts of muriate of ammonia and powdered extract of glycyrrhiza, and on one occasion, while prescribing this powder, to fulfil a special indication in the case, added four grains of quinine to each forty grains of the powder. He told the patient, who had previously taken the powder alone, of the bitter taste he had to expect, and was not a little surprised when the patient informed him that he detected no such taste whatever. Since then, Dr. Engel has tried the same combination in a number of cases, and also induced some colleagues to make use of it, and all agree that it is the best method yet discovered to conceal the bitter taste of quinine. Children usually like licorice, and as a small dose of muriate of ammonia probably never can do harm when quinine is indicated, we possess now the means of administering quinine to young children without the trouble formerly connected with this remedy. The following combination seems to be the best for the purpose:

℞ Quiniæ sulphatis,		
Ammoniæ muriatis,	ää	gr. j.
Pulv. extracti glycyrrhizæ,		gr. iv.
M.— Ft. pulvis. S.		

In the same proportion, larger doses may be given, but it does not seem to be necessary to take more than ten grains each of powdered extract of licorice-root and muriate of ammonia to ten grains of quinine, so that probably after a certain quantity of quinine, that of licorice need not be increased in the same ratio as has to be the case with smaller doses.

Persons with a sensitive palate, about two minutes after they have taken this compound quinine-powder, have a slightly bitter taste, which, however, soon ceases; besides in children, it is the main point to conceal the taste of the drug at the time they are taking it, so that if greater experience should demonstrate the fact that a few minutes after the dose has been swallowed a bitter taste appears, we still would have gained a valuable addition to our corrigents.

The muriate of ammonia and the powdered extract of licorice-root must be finely powdered and intimately mixed, and kept in a dry and warm place. There should also be first added only a little water, the same as we do in the case of flour when we wish to make a paste, otherwise the licorice swims in the form of little balls in the water, and is then difficult to dissolve. As soon as the whole — the muriate of ammonia, the powdered extract of licorice-root, the quinine, and the water — forms a homogeneous mass of syrup-like consistence, the remainder of the water, about half a tumblerful for twenty grains of the muriate of ammonia — otherwise the latter may cause griping — may be added.

INTRAVENOUS INJECTION OF SALINE SOLUTION.

DR. DMITRY O. OTT, of St. Petersburgh, has written an *Inaugural Dissertation*, which embodies the results of his extensive and prolonged experiments carried out at the respective laboratories of Professor Kronecker, Cohnheim, F. Hofmann, Kries, and J. P. Tarkhanoff. It consists of three parts, the first of which treats the question of intravenous injection of common salt; the second, that of injection of blood-serum, and defibrinated and whole blood; and the third, that of auto-transfusion (from the left carotid into the left jugular vein of the same animal). The experiments will be of interest to our readers in view of the interesting case recently recorded in the JOURNAL, in which salt solution was injected with happy effect. We make room for Dr. Ott's conclusions which are thus given in the *London Medical Record* (February 15):

From all the experiments with blood, the author draws the following general conclusion. On transfusing blood — defibrinated or whole, taken from the same animal, or from another — we cannot possibly expect that it may be inoculated to the anæmiated receiver.

On the contrary, we must regard the blood transfused as a dead body, destined for elimination out of the system in course of time. "The blood transfused dies under the influence of contact with the dead tube of the transfusion-apparatus. It is possible, however, that in future there will be invented a technical contrivance for the transfusion, under which the blood transfused will preserve its full vitality — such as the use of excised blood-vessels, instead of India-rubber or glass tubes, etc." It is not difficult to foresee the practical general corollary drawn by Dr. Ott from all his interesting experiments. "The danger from hæmorrhage," the author says, "when the loss does not exceed two-thirds of the whole mass of the animal's blood, consists in establishing a disproportion between the capacity of the bloodvessels and their contents. This danger may be obviated by introducing a certain amount of fluid, and that with pretty equal success, whether the fluid contain albumen and blood corpuscles or not. It is necessary only that it possess indifferent properties, and that it be harmless to the system. The regeneration of the anæmiated organism, and the return of the latter to its original normal condition, take place at the expense of the organism itself, since an organic fluid or morphological elements, introduced into the vessels by means of transfusion, undergo destruction, and are eliminated out of the system. However, in consequence of the fact that the destruction and elimination of all other fluids proceed more slowly than when a saline solution is used, the regeneration of the organism under the injection of common salt is attained more rapidly and more completely than under the transfusion of albuminous fluids, especially under that of blood." Accordingly, the author emphatically recommends the treatment of acute anæmia by intravenous injection of an 0.6 per cent. solution of common salt. It is only natural that he discards also injection of egg-albumen, milk, peptones, etc.

A PROPOSED INTERNATIONAL CONGRESS OF HYDROLOGY AND CLIMATOLOGY.

THE Society of Letters, Arts and Sciences of Biarritz, France, has issued invitations to a proposed International Congress of Hydrology and Climatology to be held at Biarritz during the first week in October, 1886, under the presidency of the Minister of Commerce, and assisted by the Medical Hydrological Society of Paris and the Meteorological Society of France.

The aim of this Congress is to bring together in a country rich in thermal and sanitary stations, the learned men of all countries, who would study in common the questions bearing on hydrology and climatology. All societies and scientific associations, all learned men in France and abroad, are invited to take part in this meeting.

REPORTED MORTALITY FOR THE WEEK ENDING MARCH 6, 1886.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Scarlet Fever.	Diphtheria and Croup.	Whooping Cough.

Deaths reported 2,349: under five years of age 821; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 329, consumption 323, lung diseases 332, diphtheria and croup 145, scarlet fever 44, whooping-cough 38, typhoid fever 26, diarrhœal diseases 21, malarial fever 20, cerebro-spinal meningitis 14, erysipelas eight, measles six, puerperal fever four, typhus fever three. From typhoid fever, Philadelphia 15, New York five, Cincinnati three, Boston, Lowell and Cambridge one each. From diarrhœal diseases, New York nine, Cincinnati four, Brooklyn and Boston three each, District of Columbia and Chelsea one each. From cerebro-spinal meningitis, New York five, Holyoke three, Nashville two, Boston, Cincinnati, Springfield and Haverhill one each. From erysipelas, New York three, Brooklyn two, Baltimore, Cincinnati and Holyoke one each. From measles, Baltimore five, New York one. From puerperal fever, District of Columbia three, Springfield one. From typhus fever, New York three.

In 114 cities and towns of Massachusetts, with a population of 1,376,736 (population of the State 1,941,465), the total death-rate for the week was 17.35 against 14.83 and 15.96 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending February 20th the death-rate was 24.4. Deaths reported 4,253: infants under one year of age 999; acute diseases of the respiratory organs (London) 639, whooping-cough 197, measles 79, diarrhœa 43, diphtheria 39, scarlet fever 31, fever 33, small-pox (Liverpool) three.

The death-rates ranged from 15.3 in Birkenhead to 39.1 in Blackburn; Birmingham 25.2; Brighton 19.3; Bristol 18.4; Hull 18.8; Leeds 23.51 Leicester 16.4; Liverpool 26.0; London 25.6; Manchester 28.4; Nottingham 24.9; Sheffield 18.1; Sunderland 30.7.

In Edinburgh 17.4; Glasgow 24.9; Dublin 31.8.

For the week ending February 20th in the Swiss towns, there were 38 deaths from consumption, lung diseases 30, diarrhœal diseases 11, whooping-cough seven, typhoid fever six, small-pox four, diphtheria and croup four, measles two, erysipelas one.

The death-rates were: at Zurich 21.0; Geneva 19.2; Basle 17.0; Berne 38.5.

The meteorological record for week ending March 6, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps. —

Week ending Saturday, Mar. 6, 1886.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING MARCH 13, 1886.

WOODS, GEORGE W., surgeon. Ordered to Navy Yard, Mare Island, to relieve Surgeon W. K. Scofield, April 1.

SCOFIELD, W. K., surgeon. Detached from Navy Yard, Mare Island, and wait orders.

TO THE DELEGATES TO THE AMERICAN MEDICAL ASSOCIATION.

The rates given to the Delegates to the American Medical Association meeting, May 4, in St. Louis, have been fixed by the different Railroad Committees of the country, at one and one-third fares for the round trip. Delegates must pay full fare coming, and will receive on application, from the agent at starting point, a certificate, which when signed by the Chairman of the Local Committee of Arrangements will entitle them to the reduced return rate.

No reduced return ticket will be issued unless the purchaser can show a certificate issued by the Agent from whom he purchased the going ticket, and signed by the Chairman of the Committee of Arrangements. LE GRAND ATWOOD,

Chairman Committee of Arrangements.

SOCIETY NOTICE.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH. — The third special meeting of the Fifth District Branch will be held in the Common Council Chamber, Yonkers, at 2 P.M., on Tuesday, March 23, 1886. The following scientific papers will be read: "The Physician and the Pharmacist — their Relative Duties," by J. P. Garrish, M.D. "A Case of Meningeal Extravasation with Curious Localization of Nerve-Symptoms," by A. L. Carroll, M.D. "Sacculation and Perforation of the Bladder as Consequences of Chronic Retention of Urine," by J. W. S. Gouley, M.D. J. G. PORTEOUS, M.D., *President.*

E. H. SQUIBB, M.D., *Secretary.*

DEATHS.

Died at Wayland, Mass., March 9, 1886, John McLean Hayward, M.D., M.M.S.S., aged forty-nine years.

Died in New York City, March 13, 1886, Austin Flint, M.D., aged seventy-four years. An honorary member of Massachusetts Medical Society.

BOOKS AND PAMPHLETS RECEIVED.

Ague, or Intermittent Fever. By M. D. O'Connell, M.D., M. Ch., L.M., Surgeon-Major Medical Staff. Calcutta, 1885.

Progress of Electrolysis in Surgery. By Robert Newman, M.D. Surgeon to N. W. Dispensary, New York. Read at the First Annual Meeting of the Fifth District Branch of the New York State Medical Association, Oct. 13, 1885. (Reprint from December number of Gaillard's Medical Journal, 1885.)

Report of the Commissioner of Education for the Year 1883-84. Washington Government Printing Office. 1885.

Illustrations of Unconscious Memory in Disease including a Theory of Alterations. By Charles Creighton, M.D. New York: J. H. Vail & Co. 1886.

Circulars of Information of the Bureau of Education. No. 4, 1885. Education in Japan. Washington Government Printing Office, 1885.

Hospital Sisters and Their Duties. By Eva C. E. Lückes, Matron to the London Hospital. Philadelphia: P. Blakiston Son & Co. 1886.

First Annual Report of the Pathological Department. By Francis X. Dercum, M.D., Ida V. Rul, M.D., Pathologists. (Reprinted from the Sixth Annual Report of the State Hospital for the Insane. S. E. District of Pennsylvania at Morristown, Pa., 1885.)

On the Causation and Nature of Hypertrophy of the Prostate. By Reginald Harrison, F.R.C.S., Surgeon to the Liverpool Royal Infirmary, etc.

Eighth Annual Report of the Presbyterian Eye, Ear and Throat Charity Hospital. Baltimore. 1885.

Annual Reports of the President and Treasurer of Harvard College 1884-85. Cambridge, Mass. Published by the University. 1886.

The Year Book of Treatment for 1885. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia: Lea Brothers & Co. 1886.

Reports of the Trustees and Superintendent of the Butler Hospital for the Insane. Presented to the Corporation at their Annual Meeting, Jan. 27, 1886. Providence, 1886.

Drainage for Health, or Easy Lessons in Sanitary Science. By Joseph Wilson, M.D. Second Edition with Important Additions. Philadelphia: P. Blakiston, Son & Co. 1886.

PNEUMONIA AND ITS TREATMENT.[1]

BY C. W. STOCKMAN, M.D., ANNISQUAM.

I HAVE selected for a subject to bring before you for discussion to-night, pneumonia, not with the hope or expectation of adding anything new to what has been written, but because a great change has occurred within the last two or three decades, in the views held by a majority of the profession, concerning its pathology, and consequently its treatment. The modern treatment of pneumonia, based upon expectancy, support and stimulation, appears to me to rest upon a tripod. First, the alleged discovery that the disease, instead of being the simple inflammation of the lung, attended by fever, that our fathers supposed it to be, is really a constitutional and as some would have it, an infectious and contagious disease, with a local manifestation in the lung; secondly, the assertion that the human constitution has changed within the last thirty or forty years, and will not bear depletion as it would once, and thirdly, the statement that venesection cannot cut short, or favorably modify the disease. Concerning the first of these propositions, although most of our modern text-books and teachers tell us that pneumonia is a constitutional disease, I have as yet seen only the assertion, without proof or reason being offered, and I am far from being convinced that the statement is correct. As regards the second, although I do not deny that some change may have taken place in our physical being, in the last few decades, still I am satisfied in my own mind that many of our patients might not only bear venesection without injury, but in some cases very greatly to their advantage. As regards the third proposition, I feel convinced, not only by the statements of others, but by my own limited experience, that venesection, properly applied as to time and amount, is capable not only of aborting certain cases of pneumonia and other inflammatory diseases, but that it will in some instances save the life of the patient, when nothing else will. The opponents of venesection are to be found almost wholly among those who have commenced practice in the last twenty, or at the most thirty years, and what proportion of the number, I ask, have ever bled a patient for any reason? What proportion have ever seen a person bled, or have any personal knowledge of the effect produced by venesection. They tell us that they do not bleed for fear of so weakening the patient that he will not be able to stand the exhaustion of the last stage, the stage of purulent infiltration. What proportion of the fifty thousand physicians, more or less, practising in the United States to-day, have ever once given this powerful remedy a trial to ascertain for themselves if it will so weaken the patient; if it will not rather, in many cases, cut short, or so modify the disease that it will never reach the dreaded third stage? Although there are at present many different methods of treating pneumonia, a majority perhaps of the modern school aim to reduce the pulse by veratum viride or aconite, the heat of the body by large doses of quinine, and to maintain the strength of the patient by the early, continuous, and even copious use of beef tea, milk, brandy or whiskey, and whatever else of the most nourishing food the patient can be induced to take, and all this is done in the hope that the patient will be able to bear up until all the stages have been gone through.

Says Flint in his "Clinical Medicine," "The taking of solid food should be encouraged and it should be prepared with a view to tempt the appetite; for the question is, what can the patient be induced to eat, rather than what articles of diet are allowable." Now what are the different stages, or in other words, what is this disease? Ziemssen and other foreign authors give the same description that we find in our own text books. The works upon practice for the last fifty years all give the same account of its invasion, progress and termination. First stage, congestion or inflammatory engorgement. But what is inflammatory engorgement? What is the condition of the lungs? Juergensen says: "The lungs in that stage are of a dark-red color, heavy, firm, and retain the depression caused by the pressure of the finger, showing that they contain little, or no air, but fluid; on section, the substance is found to be dense, the result of swelling of the tissue, and infiltration with a bloody serous fluid. Next comes the second stage, hepatization, marked by a very adhesive, viscous, reddish-brown, secreted fluid. This second stage is the one which is very generally present when the physician is first called, marked by a viscous, bloody, and rust-colored expectoration. Juergensen thus describes it: "The lung is now, internally and externally, of a dark, brownish-red color, solid, but easily torn; it no longer crepitates: on being cut, there usually exudes — only on pressure — a brownish-red, opaque, bloody, serous fluid. This condition, known as red hepatization, soon changes into the third stage proper, that of purulent infiltration. The cut surface is now of a straw-yellow color, and from it exudes in large quantity, a very viscid, purulent fluid, of a faint odor. It is the exhaustion of this purulent stage that the physicians who follow what they call the supporting plan, and who oppose venesection, dread.

They believe that the disease must go through its course of three stages, and therefore, instead of attempting to arrest its course, to cut it short, they limit their efforts to feeding, stimulating, watching and waiting; they do nothing to prevent the congestion which of course occupied but a small part of the lung for the first few hours —from being extended to other portions of it, or if they have not seen the case until the inflammatory engorgement has already occupied a great part, or all of the lung, do nothing to arrest its passage into the third stage — a stage from which the patient rarely recovers.

Professor Loomis in Pepper's valuable "System of Medicine" uses the following decided language: "If it is remembered in the treatment of pneumonia that the pneumonic lung no more requires treatment than do the intestinal ulcers in typhoid fever, and that we are to be governed by the patient's general condition, and not by the physical changes in the lung, as indicated by the physical signs, it is evident that all those measures which have been employed for the arrest of a local inflammatory process, have no place in our therapeutics." This *may* be the correct view. It is not for me to attempt to deny a statement made by a physician of Professor Loomis' great knowledge and experience, nevertheless, were I the subject of pneumonia, I should much prefer that measures should be taken to *attempt*, at least, to limit and control the

[1] Read before the Essex South District Medical Society.

acute inflammation going on in the lung. He continues: "It is for this reason that venesection, which at one time had its stronghold in the treatment of pneumonia has now fallen into disuse. Now the principle upon which this theory is based appears to be that the disease, like small-pox, will run a prescribed course, always the same in point of time, differing only in degrees of mildness or severity, and it is the physician's duty not to attempt to arrest its course, but to keep up the strength so as to enable the patient to bear the suppuration going on in the whole of one lung."

Loomis defines croupous pneumonia as an acute general disease, with a characteristic local pulmonary lesion. "Anatomically considered," he says, "it is an acute inflammation of the vesicular structure of the lungs, resulting in infiltration of the alveoli with inflammatory products, which renders them impervious to air."

Dr. Hiram Corson, of Pennsylvania, from whose articles upon this subject I have freely quoted, says: "I regard pneumonia as simply an inflammation of the lung tissue, and I don't worry myself to distinguish between catarrhal pneumonia and croupous pneumonia, for it makes no difference, so far as treatment is concerned, which it is; and because, too, neither myself nor any one else can tell which it is during that time when treatment is so indispensable."

Juergensen says: "It will be found very difficult and perhaps impossible to draw the distinction between a case of catarrhal and one of croupous pneumonia, if one does not see the case until consolidation is complete." When is consolidation complete? Why, in the first stage. He says of the lungs then, in the first stage: "They are of a dark-red color, heavy, firm, and contain little or no air."

Juergensen thus defines the disease; "Croupous pneumonia, anatomically considered, is an acute inflammation of the alveoli and bronchioles, in which a fibrinous exudation is poured out on the free surface of the mucous membrane and there coagulates." Says Dr. Corson, after a minute description of pneumonia "I am almost ashamed to have taken up so much space with a description of this disease, which, after all, is simply *an inflammation of the substance of the lung*," and I would ask, is there anything in this description or in any other description of pneumonia, which we meet with, to lead one to look upon it as anything more or less than an inflammation of the substance of the lung?

Now, how ought the subject of such an inflammation to be treated? Professor Loomis says: "A summary of the arguments against venesection seems to be conclusive." He tells us that indiscriminate bleeding immensely increases the mortality of the disease, and that it is especially fatal in old people and in young children, in patients of exhausted constitutions, and in those suffering from chronic diseases, and particularly from Bright's disease. No doubt, but can Professor Loomis find a physician at the present time, who advocates indiscriminate bleeding, or who would bleed a patient under the circumstances he enumerates? He further says, that it is absolutely unnecessary in the majority of cases of young adults, and also young children. I am not disposed to differ much with this statement, but when he says that in the majority of cases, it has no influence whatever, either in cutting short the disease, in lessening its duration, or in diminishing the pyrexia, though occasionally, these results *appear* to follow from its use when practised early; I should give more weight to the assertion if I could know that Professor Loomis has given venesection a fair and impartial trial. Although he further states that in the majority of cases it hinders the critical fall of temperature, and delays convalescence, and that recovery is equally, if not more rapid, when it is not practised, still he admits that in a few cases, a moderate venesection may be necessary in the early stages, to avert immediate danger of death from asphyxia.

Now, if Professor Loomis's views are correct regarding venesection, then, some of the most able and experienced physicians of the present day, who have had abundant opportunities of testing and comparing both methods of treatment, have deceived themselves in their estimate of the safety and value of this powerful remedial agent. Among the physicians of our own time, who advocate and practise bleeding, may be mentioned Drs. John Atlee, Traill Green, Austin Flint, H. I. Bowditch, J. F. Meigs, Alonzo Clark, Fordyce Barker, W. Pepper, Henry Hartshorne, and the late Professors S. D. Gross and George B. Wood; while in Great Britain, may be mentioned the late Professors Alison, Watson, Christison, Copeland, Laurence, Chambers, Parkes, C. West, Gairdner, Symonds, F. Winslow, Aitken, Markham, Handfield Jones, Dyce, of Aberdeen, Sutton, George Johnson, B. W. Richardson, and others. These are men whose opinions are entitled to great consideration, and be it remembered that, unlike most of its opponents, they have fully tested this measure, and know whereof they affirm.

Professor Hartshorne says, in relation to the treatment of pneumonia: "I am convinced by experience that prompt and moderate antiphogistic treatment may greatly lessen the danger of pneumonia, if not shorten its duration. Probably nine cases in ten would recover without the abstraction of blood; the tenth might die for want of it." The opponents of blood-letting assert that more cases of pneumonia recover under the present system of treatment. Professor Hartshorne says: "I believe that the mortality of pneumonia has increased in Philadelphia, and elsewhere, since blood-letting has been so generally abandoned." Professor Gross, and most, if not all, of those whose names I have mentioned, have expressed the same opinion. In the same connection, Hartshorne further says: "The late Dr. L. P. Gebhard, of Philadelphia, informed me that in a large practice of more than half a century, he had never lost a case of *simple* pneumonia; his treatment being (according to cases), 'moderately antiphogistic,'" as above described. Those who object to venesection in *all* cases of pneumonia, do so, almost invariably, on theoretical grounds, *without having tried it.* Its occasional use is justified with almost equal unanimity by those who have had experience with it. This was well brought out in a discussion of the subject at Richmond, Va., in 1881, the "net result" of which was thus expressed by Dr. Martin, of Boston: "I trust that it may go out to the world, that the American Medical Association sanctions the occasional use of the lancet, at least."

But let us return to Professor Loomis, who is one of the latest exponents of the modern treatment of pneumonia. He continues: "A careful study of the pathology of pneumonia, not only leads one to the conviction that venesection must do harm, but it strongly contraindicates the employment of all those remedial agents which have been used to arrest a simple pulmo-

nary inflammation." Hence, he condemns tartar emetic, veratrum viride, aconite, and all other cardiac sedatives; also calomel and antimony. Of expectorants, he says: "They have no place in the treatment of pneumonia." Counter irritation by blisters or other irritants, he condemns as of doubtful utility, though he admits that occasionally, blisters may be applied during the *third* stage, to hasten the process of resolution, and promote the absorption of plastic exudation. Carbonate of ammonia he mentions but to condemn, and digitalis, he thinks, does more harm than good; camphor and musk he pronounces inferior to alcohol, but advises champagne as a diffusible stimulant. Having thus condemned almost *in toto* the method of treatment heretofore in use, let us see what Professor Loomis recommends to take its place. He has given us the key-note to his system of treatment in the following sentence: "In all severe types of croupous pneumonia, there are two prominent sources of danger, heart insufficiency and high temperature." There are consequently, two prominent indications for treatment, namely, to sustain the heart, and reduce temperature. The essential part of the treatment itself is comprised in three words: food, stimulants, and quinine, to which he adds the administration of opium during the first four days, and the necessity of complete rest.

Those of the profession, and I believe there are many still living, who have witnessed the great and immediate relief to the pain and difficult breathing by free blood-letting at the onset, or in some cases, by the use of wet-cups only; those who have seen more than one case of pneumonia cut short, aborted in its first stage by a timely venesection, those who have watched the cough become looser and less in frequency under the exhibition of small and repeated doses of ipecac, or Dover's powder; those who, later in the disease, have noted the expectoration become freer and easier under the administration of ammonium carbonate, would scarcely be satisfied with the above line of treatment, or feel that they were doing justice to their patients.

You will ask, perhaps, what treatment I would advocate in this disease, for I do not always treat the patient as I would. In some cases, he will absolutely refuse to be bled, when his physician advises it. Again, in some cases, the patient, or his friends, will yield their consent so reluctantly, if at all; they will be so fearful of the measure, that I feel confident that if venesection is practised, and the patient ultimately dies, his death will be attributed solely to the loss of blood. But I firmly believe that in a great majority of cases, if we see and recognize the disease in its first stage — the stage of congestion — we can, and ought to arrest it. At this time, the congestion is hourly spreading further and further through the lung, and advancing to the stage of red hepatization, and I believe that prompt venesection, and that alone, will cut short the disease in many cases; nor have I, in a great majority of cases, the great fear of after-prostration, and heart failure and insufficiency, that so disturbs Professor Loomis, Dr. Reynolds, and others. In many cases, at this stage, the pulse is full, hard, and firm, and in some cases, at least, where it has lost in some degree, its force and hardness, I believe the weakness to be more apparent than real, the immediate and direct effect of a severe inflammatory disease upon a vital organ; and as the result of prompt blood-letting, such a pulse will often acquire more volume and power. It is a well-known fact that men, strong, robust, and apparently healthy, will, in two or three days after the commencement of an attack of acute pneumonia, pleurisy, or peritonitis, exhibit indications of decided weakness, depression, or rather oppression, and debility. What has dissipated their strength so suddenly? The disease has not continued long enough to cause exhaustion, and, if we can arrest it at this point, the patient will, in a few days, be as strong as before; but if we let this disease go on unchecked for a week or ten days; if we let it spread over and cripple the greater part, or the whole of one lung; if, in spite of the anorexia and the fact that the patient turns from food with loathing, we assiduously ply him with nourishment, which, in many cases, he cannot digest or assimilate; if we give him stimulants early and often, notwithstanding the fact that the greater part of one lung is engorged with blood, and the patient is the subject of an acute inflammation, with high fever, *then* I think we shall have just cause to fear exhaustion and heart-failure.

To again quote Dr. Hartshorne: "Few if any pathologists will hesitate to admit that a difference, often momentous, exists between the *exhaustion* of a system weakened by the continuance for some time of severe disease, and that *oppressive* debility with which the most robust person may be temporarily affected under the influence of an acute malady such as pneumonia, meningitis, or croup." Again he says: "The mortality of pneumonia in Philadelphia has for some time certainly increased, not in the hospitals, where the average character of the patients has always made them unfavorable subjects for depletion, but in private practice. It is not too bold an assertion, indeed, for one, who without partisanship, maintains his conviction of the occasional importance of venesection and local depletion as remedies, that while uncomplicated pneumonia, under moderate depletory treatment, was, thirty years ago, rarely fatal outside of hospitals, and not frequently so within them, the indiscriminately stimulating method, now often applied to all classes of cases, has increased very considerably the fatality of this and other inflammatory diseases, in private practice." So much for the opinion of Dr. Hartshorne, one of the most learned and accomplished physicians in Philadelphia, and I may safely add, in the whole country.

And now I want to insert a short quotation from Dr. Reynolds, the author of Reynolds's System of Medicine, which should have appeared earlier: "If the general condition be one of weakness, it matters not that the brain, the heart, or the lungs may be in a state of so-called inflammation; *the weakness is the one thing that demands immediate treatment, and to neglect its treatment* is to run the risk of sacrificing the patient to a theory of a compound state, even now but imperfectly understood." It appears to me that such teaching as this, by a man in the position Dr. Reynolds occupies, is calculated to do great harm, by misleading the young practitioner, who has not had the experience to enable him to distinguish between the *apparent* weakness so invariably present in pneumonia, and the real weakness of exhaustion from prolonged disease.

But to return to the subject of treatment. I desire to again quote Dr. Corson, who tells us in one of his articles that he has bled hundreds of patients, of all ages, and has never seen any of the injurious effects, either immediate or remote, which are so dreaded by many of the physicians of our time, nor has he ever

had cause to regret using the lancet. He says: "To me it is simply an inflammation, and I would use rapidly, as early as possible, the means which, in the practice of half a century, I have found safe and most efficient in allaying inflammation. Well, here is my patient. He had a chill hours ago; he had some pain in his side, some cough, and he feels very weak; his face is flushed, he is hot and thirsty, his pulse over a hundred and the thermometer rises to 103°; he breathes scarcely at all through the most of one lung; there is a little blood, and viscous fluid, slightly rust-colored, in the basin by the bedside; he knows how he got sick; he 'was down in the iron ore shaft all yesterday at work, came up in the evening to come home, and being in a perspiration, soon, in facing the wind, cooled off too suddenly.' I propose to bleed him, but he objects on account of his great weakness. I tie up his arm, and bleed him twenty ounces, or perhaps he feels faint by the loss of less than that. He expresses himself as being relieved somewhat of his oppression, he can lie more comfortably, he feels relieved of the fulness in the chest, but still he has a little pain in the side, or in the breast, just above the nipple. I order him one-quarter grain of sulphate of morphia; direct that a towel be wrung out of cold water, ice-water, if convenient, be applied over the affected part, to be changed frequently, or instead, a bladder of ice and water. Then ordering a mixture which contains some spirits of nitre, with about the third of a grain of morphia to a teaspoonful every two or three hours, I leave him with an express direction not to worry him by any offer of food. Next day, or even the same day, perhaps, if I find that he is not entirely relieved of the pain, and is still expectorating viscid sputa, I bleed him again freely, and if need be, cup him, and after that he is generally safe. Some one will say, 'that may do very well for your strong, iron-ore diggers, but it would prove fatal to our delicate patients.' Perhaps so, but in my experience, I have found that the weak and frail need to have the same means used to allay a toothache, or a sciatica, a pleurisy or a rheumatism, as the robust. They bear the remedies to cure an ague as well, and need them as greatly as the strongest. I have often bled the infant strangling with croup, with immediate relief; weak women with pleurisy or pneumonia, old men, and aged, very aged women, to relieve affections of the brain, or avert a paralysis."

This is the method of treatment which Dr. Corson has practised for some fifty years, and I believe it to be much nearer right than the practice now so generally adopted.

In conclusion, I would say that I would by no means advocate or practise venesection simply because a patient had pneumonia, pleurisy, peritonitis, or meningitis, but I would use it in those cases only in which I considered it safe, and better adapted than any other measure for the recovery of the patient. Its use requires experience, judgment, and discrimination, but I do believe that the weakest of our patients with primary pneumonia will better bear moderate depletion, than the most robust will bear assiduous feeding and stimulation.

After venesection, I would give to such of the more robust patients as I thought required it, small doses of tartar emetic, carefully watching its effects, but those who required it would be few. In *some* of the less robust cases, I would give small doses of ipecac or Dover's powder, and in all I would, until infiltration became complete, if the case arrived at that stage, administer opium in sufficient doses to tranquilize the nervous system, and procure sleep.

Milk I would give after the first day or two, if the patient did not object, and before that if he requested it, and more nourishing food as soon as he asked for it, but if I found indications of exhaustion coming on, and had reason to believe that he could digest and assimilate food, I should urge him to try its effect before that. If the temperature was excessive, and was not reduced by venesection, I should try to reduce it by cold compresses, or quinia, or both, and I would give my patient stimulants as soon as I felt satisfied that real exhaustion was approaching, with the first indications of failure of the heart, but I would not commence the early use of stimulants to prevent the exhaustion that *might* occur later in the case.

I will not mention other details; they are of less importance, and about which there is less diversity of opinion. In the interest of our patients I sincerely hope that this paper may be the means of inducing some one or more of my brother practitioners to investigate and test for themselves this powerful and too much neglected remedy, and if suitable cases are selected and the remedy used according to correct principles, I feel certain that they will learn to highly value the lancet, and to rely upon it in many cases of inflammatory disease.[2]

THE STAINING OF THE BACILLUS OF TUBERCLE.

BY E. W. CUSHING, M.D.

YOUR secretary, gentlemen, has requested me to supplement my last paper before this section, in which I went over the proofs of the infectious nature of tuberculosis, by a practical demonstration of the method of staining suspected sputa for microscopic examination, with reference to bacilli.

I have accepted his invitation, at some risk of wearying you, and perhaps of being considered a bacteriomaniac, since I realize how different it is to read of a practical process, from what it is to see it done. I have still in my note-book copies of descriptions of staining for tubercle bacilli, given in 1883 and 1884, by Ehrlich, Fraenkel, Ernst, and others; but it all seemed far-off, and made no deep impression on me.

I am sure it would have aroused more interest in me, for this important matter, if I had seen it done. It is curious how mythical and difficult strange chemicals seem, until one has handled them; methyl-violet seems transcendental, and vesuvin portentous, even dangerous. But when handled and used they are as commonplace as hectograph ink, or easter-egg stains.

There are many ways in which tubercle bacilli may be stained, and several in which they may be so stained as to be differentiated from all other bacilli. Some methods are easy and simple, others more complicated. In this, as in many other things, however, the easiest way is not always the best way, for it is not now a question of showing their presence when they are abundant, that is easy enough in any way: the diffi-

[2] The writer also desires to express his obligation to the article by Joseph Stubbs, M.D., entitled "Pneumonia treated by Venesection," printed in the *Philadelphia Medical and Surgical Reporter*, July 8, 1882, No. 2 of volume 47.

culty is in finding them when very few and far between, or in feeling certain that they are *absent* in a suspicious case. For this we must use the surest method, one well proved and most likely to show *all* the bacilli present.

The orthodox method for rapid staining which is usually sufficient, and which I described in my last paper, is that with aniline-oil water, methyl-violet (or fuchsin) and nitric acid, followed by vesuvin (or methylene-blue), and of this I will show you all the steps, afterwards showing another way of making a permanent test solution of fuchsin, to be used with methylene-blue as a contrast.

The only objection to the first method is that the solution is not permanent, it does not keep well. Koch says that it will keep about ten days, in a well-stoppered bottle, probably meaning in a laboratory where it is in daily and frequent use; I have tried keeping a solution in a dark bottle, excluding the light, and found it to keep very well for over a month.

Now first as to the materials. Aniline oil is a brown liquid which when fresh is colorless, but seems to be just as good when brown. It is a product of the destructive distillation of coal, a by-product of gas manufacture, or is made on a large scale by the action of reducing agents on nitrobenzol. The formula of aniline oil is $C_6 H_7 N$, and it may be considered as a phenyl ammonia ($C_6 H_5$. H, H) N., and like ammonia it forms salts with various acids.

As it was observed that bacteria took aniline dyes better when in alkaline solutions, and as in fact Koch first stained the tubercle bacilli with a solution of methylene-blue containing caustic potash, it occurred to Ehrlich to try the effect of using a solution of aniline oil instead of potash or ammonia, as the solutions of fuchsin and methyl-violet do not work well with the latter alkalies.

The results were highly satisfactory, and with some unimportant modifications Ehrlich's process has come into general use, and Koch in his last publication,[1] issued in 1885, says that he always uses it and most emphatically recommends it.

Besides aniline or aniline oil there is a similar body formed in the same way from toluol ($C_7 H_8$) that aniline is formed from benzol ($C_6 H_6$). This is called toluoidine, and may be mixed with water, filtered and used precisely like aniline.

From mixtures of these two substances various compound salts are obtained of most remarkable colors, giving the so-called aniline dyes. These are divided by Ehrlich into acid and basic, according to whether the acid or the color-base is the coloring principle, as far as concerns the election of certain tissues or microbes for the color. The so-called acid dye-stuffs, like eosine, picric acid, alizarin, etc., do not concern us here. For staining tubercle bacilli we use exclusively the basic aniline colors.

Among these are methyl-violet (chloride of trimethyl-rosaniline) in crystals and in alcoholic solution; in the last case it is very like hectograph ink, if not identical with it. The latter fluid is said to be an excellent material for staining tubercle bacilli when it is added to water to saturation. Fuchsin (chloride of rosaniline) in small crystals, and in solution, is readily recognized as one of the dyes commonly sold to stain Easter eggs. The peculiar shining bronzed appearance of either of the above when dried from an alcoholic solution is very beautiful. They both have the property of losing their color instantly when in the presence of a strong acid, as may be seen by putting some nitric or hydrochloric acid in a watch-glass which has been deeply stained by them; in fact this is the way in which the stains of these coloring agents must be removed from glasses or from the fingers.

[1] Communications, Germ. Imp. Health Office, for 1884.

Methylene-blue is a dark powder, and is used in solution of 10 gr. to ℥ i. in water. The color is intense, and is not acted on by acids. The same is true of the brown powder and solution of vesuvin.

Other aniline colors there are, many and beautiful, some of which are used for staining various bacteria or for double staining, such as eosine, dahlia-violet, etc., but these we need not now consider.

To prepare our tubercle stain we shake aniline oil ℥ ss, with distilled water ℥ x; a sort of unstable emulsion is formed, but part of the oil is really dissolved, and the turbid mixture is next filtered. To make it clear a double thickness of paper should be used, not forgetting to wet it thoroughly first, preferably in hot distilled water, in order to swell the paper. If it does not come through clear at first, or if little drops form in the filtrate, it must be run through the filter again. To this clear filtrate is added ℥i $\frac{1}{10}$ of a saturated solution of methyl-violet (or fuchsin) in absolute alcohol, and ℥i of absolute alcohol.

Aniline oil	℥ ss.
Aq. dist.	℥ x.
Shake well and filter thoroughly. Add	
Sat. alcoholic sol. methyl-violet (fuchsin) . .	℥ j. 1-10.
Absolute alcohol	℥ j.
Keep in well-stoppered bottle, preferably away from light.	

The proportion in any amount of the ingredients is 5, 20, 11, 10. Any apothecary can learn to make the solution, although the gravity of the diagnosis involved makes it very prudent for the careful man to make his staining solutions himself.

The other stains necessary are a solution of vesuvin (or methylene-blue) in distilled water 10 gr. to ℥i.

All these should be filtered on every occasion when they are used, in order to be sure that whatever bacteria we find were in the substance examined, and not in the reagents employed. For discharging the color of the first stain used, nitric acid one part, water two parts, is employed, from half a minute to three minutes, and this apparently takes out all the color, but under the microscope it is found that the tubercle bacilli have the very remarkable power of retaining their stain even when exposed to the acid. No other bacteria which can be confounded with them in practice have this power, and thus the diagnosis is made with all the precision of a chemical test.

I will say, parenthetically, that polished office tables, or those with enameled leather tops, as well as Sunday clothes, show the same remarkable tenacity for aniline colors.

The cover glasses to be used should be new, for, if used previously in looking for bacteria, it is very likely that some of the previous material will adhere to them. If old ones are to be cleaned, they should be put in strong sulphuric acid, which burns off all organic matter found on them.

A very little of the sputa is taken with a wire loop or pincers which have been first heated and then cooled, selecting especially any minute white lumps, which may be pure masses of bacilli. The little drop so

taken is laid between two cover-glasses, which are then rubbed together until the drop is quite evenly distributed. The glasses are then slid apart, not lifted from each other, but separated by sliding them in parallel opposite directions. They are then turned wet side up and allowed to dry thoroughly; they should meanwhile be protected from dust.

After this, one must remember which is the side with the sputum, for it is very hard sometimes to distinguish by sight the prepared side from the clean one. If necessary, the distinction is made by observing, when the glass begins to dry, which side is dull and lustreless and which is bright when so held as to reflect the light. The clean side will act like a mirror.

When dry and not sooner, the cover is to be passed three times, with the clean side down, through the flame of a Bunsen burner or spirit lamp, not too fast, nor yet slowly enough to scorch it. This bakes on the sputum, so that it will not wash off. Then it is laid in a watch-glass swimming clean side up on some of the first stain, here methyl-violet, and heated by passing back and forth through the flame, until little bubbles form under the cover-glass. That is the auspicious moment to stop the heat; in a moment it will boil up in a way that shocks the nerves, and the agitated hand scatters the stain over table and trousers, or the glass cracks, spreading dismay and sometimes causing profanity,—I would advise beginners to get a little porcelain dish, and, supporting that on a stand, to move the lamp back and forth under it; when the crisis comes, nervousness is less disastrous. The dish is now left to cool for some ten minutes — or, instead of the above heating of the fluid, the cover-glass may be left overnight to swim on the staining-fluid, without heating, say for twenty-four hours, and this is how sections of tissues are treated, because they cannot endure boiling; sections cut in celloidine must have the latter removed by ether and alcohol before staining for bacilli. For a negative diagnosis, that is, when no bacilli are found by the first process, and it is desired to make sure that none are present, it is well to leave some cover-glasses floating on the unheated staining solution from one day to another; also, when there is no hurry, this method saves trouble.

Next the cover-glass is taken up with forceps, not forgetting which is the prepared side, and, after rinsing in water, or preferably in 60 per cent. alcohol, is put in the nitric acid.

Instantly the color changes, it becomes light yellowish-brown and mostly disappears; when the color is nearly gone the glass is washed in pure water; here it will again become faintly violet, and if the color is feeble it is well; if, however, it is strong, the glass must be dipped in the acid again. After washing, the glass is made to swim on the solution of vesuvin, (or if fuchsin has first been used, methylene-blue is the proper contrast) for about five minutes. This removes the remaining violet color from everything except the tubercle bacilli, and stains the pus cells and any other bacteria present in the contrasting color.

The glass is now washed in water, and may be examined in water, or dried and examined in cedar oil, or dried and mounted in Canada balsam. The latter must contain no chloroform, and is best used warm, so that when cool the preparation is firm, and will not move when rubbed to remove the oil used with the immersion lens. No oil of cloves must be used, as this will discharge the color from the bacilli; this is not important for sputa, for here the cover may be simply dried and put up in balsam; but in sections of tissues it is important to use cedar oil instead of oil of cloves for clearing up the tissues. The balsam must not be heated too hot; if necessary it can be thinned with oil of turpentine or xylol.

This, then, is the full and orthodox method, as successively improved by Ehrlich, Weigert, and Koch. Fraenkel puts the acid into the vesuvin (or blue) solution, thus making two steps instead of three; it is not found to be a practical advantage, however.

Of course there has been a strong desire to have a permanent solution, and it occurred to Ziel to use carbolic acid (or phenyl alcohol ($C_6 H_5$) H O, instead of aniline oil (or phenyl ammonia).

His formula is as follows:

5 per cent. aqueous sol. of carbolic acid	100 ccm.
Fuchsin	gram. 1.
Absolute alcohol	10 ccm.
Mix and filter well.	

For discharging the color, muriatic acid one part, water two parts, is used. This fuchsin solution is quite permanent. I have used one solution for five months. I filtered it yesterday, but there was no sediment. It is used precisely as above, and gives excellent results. I show you specimens made last July with Liel's method, at the pathological institute in Vienna, where the energy of Professor Kundrat and the zeal of his accomplished assistants, Drs. Paltauf and Kolisko, both carry on a great amount of valuable work in bacteriology and offer great facilities for post-graduate study. The specimens have not faded at all as yet, and except for difficult diagnosis or cases where it is especially desirable to show that no bacilli are present, I can recommend the latter formula, which is quite in favor at the pathological institute in Vienna.

It is possible, but by no means certain that it is not so sure of finding isolated and rare bacilli, but, if found, the chemical reaction and diagnosis is just as perfect as by the first method given. There are other methods, but, as this is meant to be a practical demonstration and not an exhaustive paper, I will say nothing more about them.

A word as to microscopes. I have brought two, one with the ordinary system of lenses and illumination, including a small sub-stage bull's eye condensor. The other with oil immersion and Abbé condensor. You can observe the great superiority of the latter, and yet with the former and with a power of 400, which most microscopes give, the tubercle bacilli can be recognized.

It is fortunate that they are comparatively large, so that it is not necessary for recognizing them to have a special microscope, however desirable it may be. For those who expect to buy a microscope, for this or any other purpose, however, I would strongly recommend such a one as I show you, with a 1-12 wide angle oil immersion and an Abbé condensor; the latter is a bull's eye, flat above, about one inch in diameter, placed below the stage. It receives the light from a very large plane mirror and throws it from all sides on the highly colored bacteria, giving plenty of light with the highest powers, and, when used without diaphragms, abolishing all shadows in tissues, so that they become semi-transparent, and the bacilli can be seen below the surface of the tissue, or of the layer of sputum. With suitable diaphragms the Abbé condensor can be used

for ordinary histological work. The ordinary size can only be adapted to microscopes with a large stage, and plenty of room, but Klonne and Müller of Berlin, (Prinzen Strasse) have arranged a system to put on common microscopes, which works very well for most purposes, and is quite sufficient for finding tubercle bacilli. The cost of a 1-12 oil immersion, like this, made by Leitz of Wetzlar, is in Germany twenty-five dollars. An Abbè condensor costs half as much; you will observe that the whole system of condensor and diaphragms can be slid up and down, by which the focus can be altered so as to give the best definition for different sources of light, objectives, or oculars; usually the upper surface of the condensor should just touch the lower surface of the slide. The oil used with the immersion is equal parts of Ol. Ricini and Ol. Fœniculi, this, being of about the same angle of refraction as glass, renders correction for thickness of cover-glass unnecessary.

Perhaps it is not superfluous to say that oil, if used with water immersion lenses, will spoil them by soaking between the glasses. The specimen which I have here stained is pus from the lung of the patient whose tuberculous larynx has just been shown you by Dr. Gannett, to whose courtesy I am indebted for the specimen of lung.

The preparation is now ready, and as the Canada balsam was warm, it is already firm, now that it is cold. With a power of 400 you can see a large number of the bacilli, stained bright violet, on a yellowish-brown ground. With addition of a drop of oil and under the highest power of the immersion 1-12, and No. 3 ocular, we get an amplification of 1,000 diameters. You can see that many of the bacilli contain spores, which appear white, as they do not take the color.

Under the next microscope is a preparation of tubercle bacilli from a specimen of sputum brought me by Dr. H. I. Bowditch.

As you see, they are very distinct, and in this place there are four or five close together, although there are only a few on each slide. One slide had none, one about ten, and one perhaps twenty. The patient was a boy, who after undergoing an attack of pulmonary disease some years ago, had had now for four weeks frothy expectoration, cough and suspicious symptoms. The results of physical examination were not sufficient, in the opinion of Dr. Bowditch, to warrant a diagnosis. There was some rough respiration in right front of chest, and an obscure and uncertain dulness, with slight bronchial respiration and crepitant râle, in lower half of same lung. Altogether, however, Dr. Bowditch felt that the physical and other symptoms were so indistinct that no positive diagnosis could have been made except by finding the bacilli.

I have also here a similar preparation from sputum, sent me by Dr. Marcy, of a gentleman whose rational and physical symptoms were too equivocal to warrant a diagnosis. There was little expectoration, once slightly tinged with blood; he was in middle life, not emaciated, very active and vigorous, and attending to his business. There was a slight diminution of respiratory force at the right apex; expiration slightly prolonged; no crepitant râles.

The bacilli, though infrequent, are very distinct, and the decision by the microscope has caused the patient, by the advice of Dr. Marcy, to decide to make arrangements to go and live for a long period in a more favorable climate.

Per contra, in a specimen sent me by Dr. Knight, from a patient whose symptoms, though indefinite, were very suspicious — particularly an erosion of each vocal chord, forming in each a deep notch — I was unable to find any bacilli.

Dr. Knight stated that these deep erosions or nicks in the chords were, in his experience, seldom found, except in cases where tuberculosis was present, but here the examination of the chest gave no diagnosis, although the expectoration and the condition of the chords gave ground for anxiety.

The patient's condition improved for a time, but three months after the above examination he grew worse, with high temperatures, etc., but no clear physical signs. I now found plenty of bacilli in the sputa. He died a few weeks later.

In this bottle I have sputum sent me by Dr. Clarke, of Cambridge, from a case similar to the one of Dr. Marcy's above mentioned, where the principal symptom is profuse expectoration in a gentleman who is able to attend to his business, and has no physical symptoms from which a diagnosis can be made, although his general condition is sufficient to cause some anxiety. Here a very few bacilli are to be found, two or three on each cover-glass.

The above cases are fair samples of others which I could mention, showing the advantage of microscopic examination of the expectorations of patients even suspected of being consumptive. Of course, in well-developed cases, the disease can be readily recognized by other means of examination, such as auscultation and percussion. But in some cases, it is certain that the diagnosis can be made by the microscope several, or many, months before the disease is sufficiently developed to be diagnosticated in any other way. Who shall measure the advantages of an early discovery of such a fatal disease, in those who, by a change of climate, occupation, etc., are able to put themselves under the best conditions for getting well?

It is for this reason that I insist on the importance for practical physicians, of this method of diagnosis. I wish to compare it, in importance and usefulness, with the examination of the urine for casts in Bright's disease. Some cases of Bright's do not show casts during considerable periods; in some cases, the diagnosis can be made pretty surely without the microscope. Not every one can easily tell a cast from a roll of mucus with cells in it. But yet no one would say that he had made a real and proper examination of a patient with suspicious symptoms, until the urine had been well searched for casts.

Now, *mutatis mutandis*, all this is true of phthisis pulmonum, and my contention is that it is the duty of a physician who undertakes to make a diagnosis of the presence or absence of consumption, to examine the sputa for bacilli, except in cases so far advanced that there is no difficulty whatever by ordinary methods. It is not so very long since ordinary methods, namely, auscultation and percussion, were considered new-fangled and unnecessary; in proof, the funny verses of our venerable poet-physician, who, I believe, brought one of the first stethoscopes to Boston, at a time when the lights of those times could, as they thought, make a diagnosis easily enough from the general symptoms.

The examination of sputa by the microscope for bacilli is now taught to the students at Harvard; it is learned by those who go abroad, where they see it

used, as a matter of course, in the hospitals in all cases suspected of consumption.

Sometimes the diagnosis is difficult; careless work, or poor instruments, may make it erroneous; but the same is true of Bright's disease, and in fact, of most other diseases.

The method is not a mere craze; it has come to stay, and any one of the profession who wishes to be *teres, totus atque rotundus*, to do his very best by his cases, ought to take it up, learn it, and use it. I shall be very glad if I have here been of any service to such.

As a matter of convenience, in recording an approximate estimate of the number of bacilli found, in the average of slides examined in any case, I subjoin the scale given by Gaffky, in the Communications of the German Imperial Health Office, 1884. He divides the numbers of bacilli found on one cover-glass, prepared as above, into ten grades, as follows (it being understood that the field visible at any one time is that seen with objective 1-12 oil immersion, ocular II, giving a power of 800 diameters; the area seen is about 1-4 millimeter, or 1-100 inch in diameter):

1. In the whole amount on a cover-glass, 1-4 bacilli.
2. In several microscopic fields of view together, only 1 bacillus.
3. In every microscopic field of view, on the average, about 1 bacillus.
4. " " " " " " 2-3 bacilli.
5. " " " " " " 4-6 "
6. " " " " " " 7-12 "
7. " " " " " a good many "
8. " " " " " numerous "
9. " " " " " very numerous "
10. " " " " " enormous numbers of bacilli.

I think this scale convenient, and as nearly accurate as any method of recording or comparing can be, and, if generally adopted and understood, it will be found useful in recording examinations, and in comparing the condition of the patient at different times.

It is not necessary that the sputa be examined at once when collected. The bacilli stand ordinary putrefactive changes in their environment very well. The sputa may be kept or sent from one place to another either in a vial, or by being dried and baked on to cover-glasses, as I have showed you to-night. The addition of a weak solution of carbolic acid does not interfere with the coloring, but is not necessary, except to prevent unpleasant odors.

In reply to the question as to what amount of examination seems necessary in order to say that the bacilli are *not* present, I would say that, in a doubtful case, I think it sufficient to prepare three pairs of cover-glasses, using the quick method with two pairs, and leaving the other two glasses to swim, until the next day, on the unheated staining fluid. If no bacilli are found in the six glasses thus examined, another examination, or even two, should be made at intervals, just as is customary in searching for casts in Bright's disease.

If still no bacilli are found, it is pretty safe to infer that the patient has not, at that time, pulmonary tuberculosis (unless it be acute miliary), although theoretically, it is possible that the bacilli may be in the lungs, and have no access to the bronchi; but for ordinary phthisis, or consumption, the diagnosis can be made with practical accuracy.

Hotel Pelham, Boston.

REPORT ON MEDICAL CHEMISTRY.

BY WILLIAM B. HILLS, M.D.

ARSENIC.

In cases of suspected arsenical poisoning, it is sometimes a question whether any poison found was taken into the body during life or was introduced after death. This question arose in a case which was tried a few years since in Michigan.[1] A lady died with symptoms which strongly suggested irritant poisoning. The body was exhumed one hundred and five days after death. Prof. A. B. Prescott found about twenty grains of arsenious oxide in the stomach and rectum together, and he calculated from an analysis, that the whole liver contained from six to fifteen grains, according to the size of the organ. The body was again exhumed later, and the brain and a portion of the muscles of the calf of the leg examined; in these no arsenic was found. The husband claimed to have injected arsenious oxide suspended in water into the mouth and rectum for the purpose of preserving the body. The six experts in the case were equally divided on the question "granting that the arsenic was injected into the mouth and rectum in the manner claimed, could it reach the liver and other organs outside the alimentary canal?"

Drs. Vaughan and Dawson made some experiments at this time, which showed that, when arsenious oxide was injected into the mouth and rectum after death, it was so far diffused that at the end of twenty-five days it could be detected in the liver, heart, spleen, kidneys and brain.

More recently, Mr. Frank S. Sutton has made a series of experiments on this subject in the laboratory of Professor Wormley, the bodies of dogs killed with chloroform being employed.[2] In each case three grammes of arsenious oxide suspended in fifty cc. of water were injected into the stomach, and an equal quantity of the oxide in ten cc. of water into the rectum. The body was then buried in the earth. In four cases, in which the injections were made in from twenty-three to twenty-six and one-half hours after death, and the bodies exhumed at the end of one hundred and two, seventy-four, forty-four and eighteen days respectively, arsenic was found in the liver, kidneys and brain. The quantity of arsenic was larger the longer after the introduction of the poison the body had been buried. In the most protracted case ten milligrammes of arsenious oxide were found in the liver.

Even when the injection was made ten minutes after death and the body examined at the end of three days, the final solution from the brain gave a well-marked stain in the reduction-tube of a Marsh apparatus, and satisfactory evidence of the presence of the metal in the liver and kidneys was obtained. But when the injection was made twenty-four hours after death and the body examined at the end of three days, the final solution from the brain furnished only the faintest trace of arsenic. The metal was present in very minute quantity in the liver, but it seemed to be entirely absent from the kidneys. These experiments show that, when the injection is made very soon after death, the diffusion takes place more readily than when the injection is not made until some hours after death.

This question of the *post-mortem* diffusion of arsenic

[1] American Journal of Medical Sciences, October, 1883, page 390.
[2] Wormley's Micro-Chemistry of Poisons, Second Edition, page 311.

is of great importance and is liable to arise in any case of suspected arsenical poisoning. Embalming fluids containing arsenious oxide are employed very frequently by undertakers for preserving bodies after death. These fluids are injected into the mouth and rectum and sometimes into the abdominal and pleural cavities. Experiments thus far made justify the conclusion that chemical analysis, even of the most remote organs, as the brain, will not enable the expert to say that the arsenic found was introduced into the body before death.

MM. Brouardel and G. Pouchet [3] have made a series of experiments relative to the elimination of arsenic through the milk. They gave to nursing mothers Fowler's solution, in doses of two drops gradually increased to twelve drops daily. No bad symptoms followed in any case, but an appreciable quantity of arsenic was always detected in the milk. The milk of one woman who took twelve drops of Fowler's solution daily for six days contained one milligramme of arsenic in each one hundred grammes. Experiments on animals gave similar results. Their young in many cases died, and analysis showed the presence of arsenic in their bodies. The conclusion is reached that it is not prudent to administer arsenic to nursing mothers except in cases of absolute necessity.

These investigations were suggested by a case of suspected arsenical poisoning. A man was accused of having attempted to poison his wife by administering to her arsenious oxide. The attempt was unsuccessful, but her nursing child, two months old, was attacked with vomiting and diarrhœa, and died in forty-eight hours. The body of the child was exhumed after the lapse of several months and was found almost wholly converted into adipocere. The skin was intact. The whole body, which weighed only two kilogrammes, was subjected to analysis, and was found to contain a relatively large quantity (five milligrammes) of arsenic. The experts considered it possible that the arsenic was introduced into the child's system through the milk of the mother.

Schlagdenhauffen and Garnier [4] have made some investigations, the results of which confirm those obtained by Orfila in 1847, and prove that bodies buried in an arsenical soil cannot receive any arsenic through the medium of rain water percolating through the soil. Arsenic is found in many soils, especially in red sandy soils, in which it probably exists as ferric arseniate. This compound is slightly soluble in boiling water, but is quite insoluble in cold water, and cannot be extracted by rain water percolating through the soil. If an aqueous solution of any compound of arsenic is left in contact with a clayey soil containing lime or iron at the ordinary temperature, the arsenic is gradually converted into insoluble compounds which are retained by the soil. Any arsenical compound introduced into such a soil, and subjected to continual infiltration of rain, if originally insoluble, remains insoluble; but if soluble, it gradually becomes insoluble, and at a depth of 0.6 — 0.9 m. from the point at which the arsenic is introduced, no arsenic can be detected in the infiltered water, even after fourteen months.

STRYCHNINE.

P. C. Plugge [5] contributes an interesting article on the elimination of strychnine. The author sometime since obtained from strychnine, by the action of potassium permanganate, an amorphous oxidation product, which has the properties of an acid and to which the name strychnine acid (strychninsäure) is given. The present investigation was undertaken for the purpose of ascertaining whether this oxidation product is also formed from strychnine in the system. Incidentally, however, several other questions were considered. The paper is of such length that we can give only the more important results of the author's investigations:

(1) Sonnenschein's reagent is the most delicate for both strychnine and strychnine acid.

(2) Chloroform is to be preferred to benzol for removing strychnine or the acid from aqueous solutions or from urine.

(3) Strychnine acid passes through the system in whole or in great part without undergoing any change. It can be detected in the urine passed two hours after the administration of two milligrammes of the acid.

(4) Strychnine passes through the system in great part without undergoing change. It can be detected in the urine passed two hours after the administration of one milligramme of strychnine sulphate.

(5) As a result of the exceedingly poisonous character of strychnine and the small doses which must necessarily be administered to avoid a fatal result, it is not possible at present, that is, until we have at our disposal more delicate analytical processes and tests, to show whether all the strychnine passes through the body unchanged, or whether a portion is decomposed.

(6) The elimination of strychnine takes place relatively slowly; traces of the alkaloid can be detected in the urine eight days after the administration of a single dose. This fact should not be forgotten in prescribing strychnine. When the administration of small medicinal doses is continued for a considerable time the alkaloid accumulates in the system and symptoms of poisoning follow.

SULPHURETTED HYDROGEN.

P. Brouardel and P. Loye [6] have made experiments for the purpose of discovering, if possible, the cause of the variation in the symptoms observed in cases of poisoning by sulphuretted hydrogen. Dogs were allowed to breathe mixtures of air and sulphuretted hydrogen containing 2 per cent. and 0.5 per cent. of the latter gas. In the first case, death usually took place in two or three minutes; in the second case in from 17 to 50 minutes. The authors conclude that there are two forms of sulphuretted hydrogen poisoning. In one, death is sudden, and is due to action on the nervous centres; in the other death takes place slowly, and is due to asphyxia combined with action on the nervous system. The poisonous action is influenced more by the tension of the gas in the air than by the absolute quantity. A dog died in two minutes after breathing 5 litres of a 2 per cent. mixture; a second dog lived forty-five minutes after breathing 100 litres of a 0.5 per cent. mixture.

Dr. G. A. Smirnoff has made extended experimental researches on the action of sulphuretted hydrogen on the animal system. A summary of the results of his investigations may be found in the *London Medical Record*, November 16, 1885, page 472.

POTASSIUM CHLORATE.

Schack [7] recommends the following process for the quantitative estimation of this salt in urine. The urine is completely precipitated with basic acetate of lead; the filtrate is freed from lead by means of sulphuretted hydrogen, again filtered, and warmed until the excess of sulphuretted hydrogen is removed. Upon evaporating the resulting colorless liquid to the point of crystallization, a small amount of the salt separates. The mother-liquor is diluted with water up to twenty-five cubic centimetres and five cubic centimetres are titrated with deci-normal silver solution. To another five cubic-centimetres, a few drops of solution of sodic carbonate are added; the solution is then evaporated to dryness, gently ignited, and extracted with water; in this solution, after neutralization with nitric acid and addition of potassium chromate, the chlorine is estimated with deci-normal silver solution. From the difference in the amount of chlorine obtained by the two titrations, the amount of potassium chlorate contained in the mother-liquor can be calculated. The salt could not be detected in blood which had undergone putrefaction.

J. v. Mering [8] confirms Marchand's view that potassium chlorate converts the hæmoglobin in the blood into metahæmoglobin, thus rendering the blood useless for the process of respiration. This action is dependent on the amount of chloric acid present, which has just the same effect as the salt.

THE POISONOUS CHARACTER OF URINE.

Considerable attention has been given to this subject during the past few years, and many attempts have been made to determine the constituent of urine to which its toxic effect is due. Bouchard [9] found that it required much more urea to kill an animal than was contained in a poisonous dose of urine; that uric acid was nearly harmless, as were also the extractive matters; that the potassium salts, though poisonous, were not so in the small quantities contained in the urine injected; that the urine lost half its toxic power when decolorized with animal charcoal, and that the poison was not volatile. Lépine and Aubert [10] have recently studied the relative toxic effect of the organic and saline constituents of the urine. Two dogs of the same species and as nearly as possible the same size were taken, and into the femoral vein of one of them a quantity of urine was injected just sufficient to cause death. A second larger quantity of urine was evaporated to dryness, the residue incinerated, the ash dissolved in a volume of water equal to the volume of the original urine, and this solution injected into the femoral vein of the second dog until death resulted. With normal urine, if 60 cc. per kilo. of the dog's weight were sufficient to cause death, a slightly larger quantity, about 65 cc. of the solution of the ash was sufficient to produce the same result; in other words, in normal urine, 85 per cent. of the total toxic effect is due to the saline constituents. With febrile urine, however, the results were very different. If 25 cc. of urine per kilo. were sufficient to cause death, a much larger quantity, about 40 cc. of the solution of the ash was required to bring about the same effect; in febrile urine, therefore, only 55 per cent. of the toxic effect is due to the inorganic salts. The symptoms produced by febrile urine are different from those produced by normal urine; the former may produce violent clonic convulsions, whilst the latter always kills by stopping the action of the heart.

ALKALOIDS IN URINE.

According to Bouchard and Pouchet, normal urine contains substances of an alkaloidal nature. Villiers,[11] however, maintains that alkaloids are not present in normal urine, but that they are constantly present in the urine of persons suffering from certain diseases and even in the urine of persons suffering from slight indisposition only. They have been found in the urine of various acute diseases: for example, typhoid fever, pneumonia, rubeola, diphtheria, cholera. They are probably formed in some of the organs of the body and passing from these into the circulation, are eliminated through the kidneys. Villiers suggests that they may be the cause of death in certain cases, owing to the fact that they are formed more rapidly than they are eliminated; and he considers that the ingestion of large amounts of water may in many cases prove beneficial by facilitating the elimination of these alkaloids.

Hospital Practice and Clinical Memoranda.

AN ANALYSIS OF 412 CASES OF LOBAR PNEUMONIA, OCCURRING AT THE MASSACHUSETTS GENERAL HOSPITAL BETWEEN JANUARY 1, 1870, AND DECEMBER 31, 1885.[1]

BY CHARLES W. TOWNSEND, M.D., LATE MEDICAL HOUSE OFFICER.

THE following analysis has been made from the records of the hospital for the last fifteen years, excluding only those cases dying within twelve hours of entrance. Fractions in the percentage figures have generally been omitted, everything above one-half counting for an additional unit, everything below one-half being neglected.

Hospital statistics on disease are objected to [2] as not giving on some points a true picture of the disease such as would be found in statistics from private practice, which include all classes of society. Thus hospital mortality is increased by the fact that severe cases are more likely to be sent there, and cases whose destitution or intemperate habits have left them without other refuge than the hospital, while the more thrifty are cared for at their homes. But on the other hand many rapidly fatal cases are debarred from the hospital from their very rapidity. That the age of young adults is the most common age for this disease in the hospital may be partly explained by the fact that at this age men in the lower classes are frequently without homes and depend on their daily labor, and are hence sent to the hospital in severe illness. Younger men and children are still taken care of by their parents, while older men may have made homes for themselves unless they are thriftless, which generally means intemperate, and this latter fact may partly account for the great mortality in the older men. Bearing in mind these limitations, the following statistics are given for what they are worth.

Of the 412 cases, 311, or 75¾ per cent., recovered,

[1] The hospital records were examined with the permission of the late resident physician Dr. Whittemore.

[2] Juergensen Croup. Pneumonia, in Ziemssen's Cyclop. American trans. Vol. v.

and 101, or 24½ per cent., died. The mortality found by the British Collective Investigative Committee[3] on 1,066 collected from private practice in the British Isles is a little over 18 per cent.

In the following table the number who recovered and died at different ages is shown, those under ten years being omitted, as there were only two, of whom one recovered and one died.

Age.	Recovered.	Died.	Total.	Death per ct.
10–19	40	5	45	11
20–29	114	25	139	18–
30–39	81	18	99	18+
40–49	46	19	65	29
50–59	18	20	38	53
60–69	7	8	15	56
Above 70	3	5	8	63

This would show that the age of greatest frequency is in the young adult from which point the frequency steadily diminishes while the rate of mortality increases as age advances. The following charts show at a glance these facts.

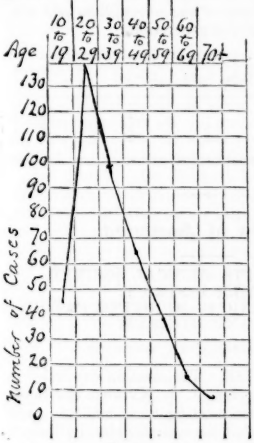

Fig. 1.

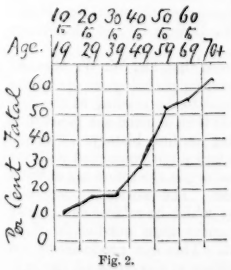

Fig. 2.

As to sex 217 males recovered and 71 died, mortality 25— per cent., and 88 females recovered and 28 died, mortality 24+ per cent. The much larger number of males (more than twice as many) may be partly due to the fact that they are more likely to be taken to a hospital than females, but the British Statistics[4] from outside practices show a nearly equal preponderance of male, namely, 704 males to 356 females. The mortality, which is usually stated to be higher in females, here practically the same in the two sexes, in the British Statistics the male mortality being 14.2, the female 09.9.

The previous condition of patients as to health and alcoholic habits were unfortunately often passed over in silence in the records, but the following table includes those cases where these points are mentioned.

Of the "delicate" who recovered, 1 had heart disease, 4, phthisis, and 1, Bright's disease; of those who died, 3 had heart disease, 1, phthisis, 3, Bright's disease, 4, asthma, 1, marked lateral curvature, 1, Pott's disease, and 1 was an idiot.

[3] Collec. Invest. Rec., Vol. II.
[4] Loc. cit., page 30.

Previous Condition.	Recovered.	Died.	Total.	Death per ct.
Good Health . .	201	37	238	16
Delicate	45	21	66	32
Temperate . . .	35	6	41	15
Intemperate . .	25	17	42	40

Of 205 cases, 138 were said to follow exposure, and 67 occurred without known exposure; in the other cases no mention is made of this point, and it seemed probable that a majority of these were without exposure, because patients are generally extremely anxious to state the ætiology in a disease supposed by them to be due to catching cold.

The prevalence in different months is shown as follows.

Month.	Recovered.	Died.	Total.	Death per. ct.
January	38	9	47	19
February	27	11	38	29
March	34	19	53	36
April	58	15	73	21
May	42	5	47	11
June	7	9	16	56
July	12	3	15	20
August	6	2	8	25
September . . .	14	0	14	0
October	17	6	23	26
November . . .	31	9	40	23
December . . .	27	10	37	27

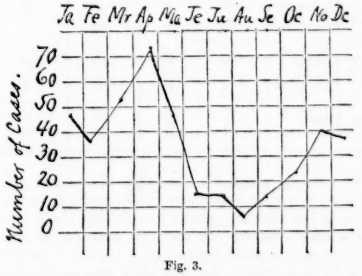

Fig. 3.

In the following table portions of the lung are arranged in the order of the frequency with which they are affected by the disease.

Seat.	Recovered.	Died.	Total.	Death per ct.
Lower right lobe .	112	13	125	10
Lower left lobe .	68	7	75	9
Both lungs . . .	38	27	65	42
Whole right lung	34	22	76	39
Upper right lobe .	34	10	44	23
Whole left lung .	12	11	23	48
Upper left lobe .	10	7	17	41

This agrees almost exactly as far as the order of frequency is concerned, with the English analysis, the only difference being that portions of both lungs as shown by that analysis are more frequently affected than the lower left lobe. The relative fatality of the different portions of the lung affected is of much less value, owing to the small number of cases. This is shown by comparison with the English list arranging the tables in order of fatality.

Mass. General Hospital.		Collective Investigation.	
Whole left lung,	48 per cent.	Both lungs,	30 per cent.
Both lungs,	42 "	Whole right lung,	28 "
Upper left lobe,	41 "	Whole left lung,	17+ "
Whole right lung,	39 "	Lower left lobe,	17— "
Upper right lobe,	23 "	Upper right lobe,	13+ "
Lower right lobe,	10 "	Lower right lobe,	12— "
Lower left lobe,	9 "	Upper left lobe,	12— "

Both analyses agree in making affections of both lungs, the whole of either or the left apex most fatal, while the right apex and the two bases are much less fatal.

An examination of the records as regards symptoms show that of 325 cases in which mention was made, 207 had a marked chill or rigor, 61 chilly sensations only, and 57 were stated to have had neither. Of 374 cases, in 366 thoracic pain was present at some time in the disease; in 8 it was absent. Cough was mentioned in 399 records, stated to be absent in 3, and present in 396; in 106 of the latter it was noted as slight. Expectoration was absent in 21 of 383 cases and present in 362; in 121 of the latter it was said to be slight. Of 341 cases in which the character of the expectoration was noted, in 278 it was bloody or rusty, and in 63 blood was absent. In 343 cases there was a record of the temperature, in 333 of the pulse, and in 307 of the respiration, and an analysis of these give the following results:

		Recovered.	Died.	Total.	Death per ct.
Temp.	Below 102°	56	12	68	18
	102°–104°	133	37	170	22
	Above 104°	68	37	105	35
Pulse	Below 100	55	2	57	4—
	100–120	126	15	141	11
	120–140	61	28	89	31
	Above 140	6	40	46	87
Resp.	Below 40	141	13	154	8
	40–60	79	56	135	41
	Above 60	7	11	18	61

For value in prognosis the table shows the small mortality when the pulse does not exceed 120 beats in a minute, the mortality slightly exceeding the average with a pulse between 120 and 140, and the enormous mortality with a pulse above 140. With a respiration below 40 in a minute the mortality was small, above that, large.

The termination of the disease was in 128 cases by crisis, in 84 by lysis. The 8th day was the one during which crisis most frequently occurred, this being the fact in 24 cases. In 22, the crisis came on the 9th day; in 16, on the 7th day; 12 on the 10th day; 11 on the 12th day; 9 on the 6th day; 8 on the 11th day; 6 on the 5th day; 4 on the 13th day, and 1 on the 14th day; in 5 crisis took place in the 3d week, and in 5 during the 4th week.

The favorite time for lysis was in the 3d week, 13 taking place then; 7 reached normal by lysis in the 4th week and also on the 11th day; 6 on the 9th and 13th day; 6 on the 12th day; 4 on the 8th day, and also in the sixth week; 3 on the 10th day, and also in the 5th week; 2 on the 7th day, and in the 7th week, and 1 each on the 14th day and 9th week.

In 74 cases in which the day of death was found, in 11 it occurred on the 8th day; in 9 on the 9th day; 7 on the 11th day; 6 on the 10th, and also on the 14th day; 5 on the 6th day; 4 on the 7th day; 3 each on the 12th, 13th, 15th, 16th and 17th days; 2 on the 5th and 25th days, and 1 on the 18th, 19th, 20th, 24th, 30th, 35th, and 60th days.

A thorough examination of the treatment was not attempted. Stimulants, generally in the form of whiskey or brandy were given in nearly 200 cases, including nearly all the fatal ones. A nourishing liquid diet, given more systematically in late years. Bleeding in not more than 4 or 5 cases; squills and tartrate of antimony in a very few cases; ipcac in small doses in a moderate number. In a word, the treatment, more especially of late years, was sustaining and expectant.

Complications: 23 cases were complicated with a well marked pleural effusion; of these three died. 8 had also typhoid fever, of whom 3 died. 12 were complicated with delirium tremens and 3 died. 2 had acute rheumatism and 1 died. 2 had pericarditis and 1 died; 1 empyema and died: 1 peritonitis, and 1 intermittent fever, both recovering. The chronic diseases complicating the cases have already been mentioned.

There are records of 29 autopsies, and the following table shows the condition of the spleen, liver and kidneys as regards granular degeneration.

	Gran. degen.	Normal.	No mention, or doubtful.
Spleen	17	10	2
Liver	9	11	9
Kidneys	11	10	8

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

FEBRUARY 10th, 1886. The meeting was called to order at 8 o'clock, by DR. F. I. KNIGHT, Chairman. The records of the last meeting were omitted. The chairman announced that the committee on the finances of the Section, which was to have been appointed at the last meeting, had been chosen after the meeting, and consisted of the following gentlemen: Dr. Henry C. Haven, Dr. Vincent Y. Bowditch, and Dr. Albert N. Blodgett.

The Chairman announced that Dr. W. W. Gannett would exhibit some interesting pathological specimens before the Section, previous to the reading of the regular papers. Dr. Gannett then showed the heart of a patient with the following outline history. The patient had died from some cause not connected with the heart, but on opening that organ the following unusual conditions were observed. The aortic orifice was the seat of obstruction, by which its calibre was greatly reduced. Probably not more than one-fourth of its normal lumen was patent. This was produced by the fusion of the adjacent borders of the cusps of the aortic valves, in such a way that only a central orifice large enough to admit a lead pencil existed in which the blood could reach the aorta. An unusual feature about the case was the fact that the left ventricle was not the seat of hypertrophy as would naturally be expected

under these conditions. The ventricle usually becomes hypertrophied from the increased labor required to force the blood through the obstructed orifice, and the heart thus performs its function by the expenditure of an abnormal amount of force. When the heart has reached the limit of compensatory hypertrophy, its ventricle begins to yield to the strain, and we have dilatation in conjunction with the hypertrophy. Here, however, no dilatation is to be observed. This is due to the fact that there is also a concomitant disease of the mitral valve, by which the blood was allowed to regurgitate in part back into the left auricle, upon each contraction of the left ventricle. This condition was due to the thickening of the substance of the mitral valve, and to a shortening of the chordæ tendinæ, so that the mitral valve could not completely close the auriculo-ventricular orifice, and consequently a portion of the blood in the ventricle was with each pulsation allowed to return into the auricle. Thus the unusual condition arose, of extensive stenosis of the aortic orifice, with all the objective phenomena of obstruction at this point, but unaccompanied by the usually associated hypertrophy of the left ventricle. There was, however, marked dilatation of the right ventricle due to the backing of the blood from the left auricle, owing to the defective condition of the mitral valve. The case presents many interesting features, as it comprises in one specimen the conditions of stenosis of the mitral and of the aortic orifices, without hypertrophy of the left cavities of the heart, but accompanied by dilatation of the right ventricle.

Dr. Gannett also showed a specimen of fluid taken from the abdominal cavity of a female patient who died at the City Hospital. The case was interesting from the fact that the fluid bore a great resemblance to milk, both in color, consistence, and in the fact that it held in suspension a large quantity of fat in small globules. There has been no decomposition in the fluid though several months have elapsed since it was removed. The characters of the fluid are those of chyle, and the attention is at once directed to the distribution of the chylous channels as a possible key to the existence of so singular an effusion. It must be borne in mind that the lymph and chyle from the lower limbs and from the abdomen as well as from the left thoracic cavity is collected by the lymphatics of the thoracic duct, which empties into the left subclavian vein; while the lymph from the right side of the thorax and from the head empties into the right subclavian vein by a separate duct. The indications, therefore, were those of some obstruction to the flow of the chyle through the thoracic duct of the left side. Upon investigation there was found to be a thick and resistent projection into the lumen of the innominate vein, whereby the calibre of the vein was reduced to less than half its normal size, and the flow of blood must have been impeded to this degree, through this vessel. At a point just beyond the point of obstruction was observed a thrombus, situated at the junction of the internal jugular vein and the innominate vein. The thrombus occupied the entire lumen of the vein and extended beyond the point of entrance of the thoracic duct, thus entirely occluding its calibre. The chyle, therefore, was effused into the abdomen, into the left thoracic cavity, and occasioned disturbance in the nutrition of the lower extremities. The cases of obstruction of the thoracic duct which had been reported have been mostly associated with some form of skin diseases, generally scleroderma, which has thus come to be regarded as one of the indications of this condition, and strangely enough, the patient from whom the present specimen was derived entered the hospital on account of ulceration of the right leg.

In cases, therefore, in which an effusion occurs in the tissues of the lower limbs, in the abdomen and in the left pleural cavity, the possible existence of an effusion of chyle from obstruction of the thoracic duct should not be forgotten, this increases; to almost certainty, if on aspiration the fluid is found to be milky and to contain fat in suspension.

Dr. Edes asked if "chylous urine" existed in this case. Dr. Gannett stated that this feature had not been noticed.

Dr. Gannett then showed the larynx from a patient who had recently died in the hospital, in which an extensive tubercular ulceration had occurred. The disease was bilateral, almost symmetrical, and had extended from the tip of the epiglottis through the entire body of the larynx and to a depth of 6 cm. into the trachea. Over this entire area the mucous membrane was destroyed, the vocal cords had partially disappeared and the surface was composed of a grayish tissue, upon the surface of which, and in the substance of which could be seen numerous small grayish or grayish-yellow prominences. These were situated upon an irregular eroded surface, in which numerous ragged depressions existed where the loss of substance was even more extensive than elsewhere. . . . The patient had been aphonic for some time before death. The case was made more interesting by a preparation of a microscopic specimen of tubercle of the larynx, which was examined under a microscope in the hall. The bacilli were abundant, and were plainly visible to all present.

Dr. Blodgett asked if there was any extension of the disease into the structures surrounding the larynx and trachea? He had seen one case in which the sternomastoid muscles and the connective tissue adjacent had become infiltrated by tubercle, but he had never seen a case in which the local changes due to tuberculosis were so extensive or so striking. Dr. Gannett stated that the extra laryngeal tissues were not noticeably invaded though the primary seat of the disease was the pulmonary tissue, and there was extensive destruction of the lung structure from its ravages.

THE STAINING OF THE BACILLUS OF TUBERCLE.[1]

Dr. E. W. Cushing gave a detailed and careful description of the method employed by Koch in the detection of the bacillus of tuberculosis.

Dr. Cushing stated that the cover glasses should be new or that the same covers should not be used a second time, owing to the difficulty in cleaning them, as it is quite easy for some of the previous specimens to adhere to the covers, where it cannot be easily observed; if covers are to be cleaned they should be immersed in strong sulphuric acid, which effectually oxydizes all organic matters and renders the glasses chemically clean. . . . In the examination of suspected sputum, a small portion of the adherent mass, preferably a small fragment of the lumpy part of the expectoration should be placed upon a thin cover glass and another cover should then be firmly pressed upon it so that the sputum is confined between the two covers.

[1] See page 268 of Journal.

The covers should now be slid one upon the other, until the sputum has been evenly pressed smooth and in an exceedingly thin layer between them. The glasses must be dried thoroughly, at a gentle heat. The cover is then to be passed three times slowly through the flame of an alcohol lamp or through that of a gas burner in order to coagulate any albumenoid matters, and remove any traces of moisture. The cover is then allowed to swim upon a small quantity of the color, (in this case methyl-violet in aniline oil was used), and the specimen is left for twenty-four hours to become impregnated with the tint. Or the coloring may be hastened by heating the solution to nearly the boiling point, when small bubbles may be seen forming upon the lower side of the cover-glass, which is the indication that the heat must be removed. The cover should then be quickly washed in distilled water, and placed in a mixture of one part of strong nitric acid in two of water, where the specimen should be left only so long a time as is sufficient to discharge the color from the slide. This is generally a matter of a few seconds, and the cover should again be washed. The specimen is then allowed to swim upon a solution of vasuvine (or if fuchsin was employed as the first tint, then methyl-blue is used as the contrast). Again, after rinsing, the slide may be placed under a microscope with nothing but water, or it may be dehydrated by alcohol, and then treated with cedar oil to clear it, when it is ready to be mounted in balsam. The balsam must be pure, and free from dilution, especially with chloroform or with oil of cloves, as these discharge the color from the bacilli. The bacilli then appear as small "stæbchen" of the color of the first solution, while the field is tinted with the second color. The best results are undoubtedly obtained by using an "Abbé condensor" and a one-twelfth oil immersion objective.

The importance of the detection of the bacilli of tuberculosis in cases of pulmonary disease, especially in those early stages in which the existing physical signs afford no positive indication of the nature of the lesion, cannot be overestimated. The examination of the sputum in cases of any pathological process affecting the respiratory passages is now a recognized feature of clinical investigation with many of the most eminent practitioners abroad, and should certainly be made an integral part of the instruction of those who are to have the care of the sick. The bacillus now occupies the same position in regard to pulmonary disease that casts hold in relation to disease of the kidneys, or that auscultation and percussion hold to phthisis. This is taught in the medical colleges, but the profession is not yet familiar with it as an element of every day experience in the investigation of clinical conditions. There can no longer be any doubt that it forms a most useful "control" in weighing the value of other clinical phenomena from the aggregate of which a scientific diagnosis is reached. It is true that tubercles may exist in certain cavities which may not communicate with the bronchi, but in the vast majority of cases the expectoration in pulmonary tuberculosis may be said to offer a key to the character of the disease which has produced it.

Upon one point in respect to tubercle there is yet a great deal of confusion, and this is in relation to the estimation of the gravity of the prognosis to be given, from the relative number of bacilli observed. Professor Gaffky has made a table, by which a scale of the relative abundance of the bacilli is shown in a graded frequency from one to ten.

It is desirable that some standard of relative frequency should be adopted for general use in bacillary examinations, and that of Gaffky seems the best one which has yet been proposed.

DR. H. C. ERNST, of Jamaica Plain, stated that he had been an interested listener to the paper of Dr. Cushing, and that while he agreed with the main part of the essay there were some points in which he must differ from the reader. He said that Dr. Cushing has very properly called attention to the fact that it is a necessity that the physician should be able to examine suspected sputum or other material as a regular part of the clinical investigation of disease, at the bedside, or in his own office. The first requisite to successful work in this direction is a microscope adapted to this particular and special kind of investigation. Not every microscope will do this, and to do it well any microscope requires certain particular and unusual accessory apparatus, adapted to procure effects not heretofore considered requisite or desirable. This fact was recently illustrated at a scientific meeting in another State, at which an exhibition of the bacilli of tuberculosis was announced, as a part of the programme. The members had made sections and found bacilli, using the Hartnack microscope without sub-stage illumination as is now thought necessary by means of the Abbé condensor. The president of the Society afterwards brought the specimens to Dr. Ernst for corroborative examination, who failed to detect the bacillus in any of them. The error in observation was due to the fact that crystals were present in the specimens, and these were mistaken for bacilli. These existed in the aniline oil that was used, which had not been previously filtered. The best microscope is not adapted to the examination of bacilli without a sub-stage condensor. This is the "sine qua non" of the study of bacilli. The examination may be a matter on which hangs the life or death of the patient, and should not be undertaken without all the necessary apparatus to insure accuracy of results. The technique of staining may be varied in many ways. The value of this proceeding consists in the fact that the bacillus of tuberculosis retains the color of the staining substance in the presence of nitric acid, while the other parts of the specimen become clear by the discharge of the stain from the action of the acid. . . . The diagnosis in respect to the bacillus tuberculosis depends entirely on the color, and the microscope is the only means of forming a diagnosis. . . . The short method of staining is not reliable, especially in test cases, for it is subject to errors which are avoided in the longer exposure of the suspected material to the coloring agent. By the quicker method, some cases will unavoidably escape detection, which might be an accident of the most tremendous importance to the patient. It is unquestionably better to leave all specimens in the staining fluid for twenty-four hours.

In regard to the preparation of the color-reagents, Dr. Koch told the speaker a short time ago that the watery solution of fuchsin is equally effective with the alcoholic solution, and that is the form in which this color is now used in the laboratory of that distinguished observer. The solution of nitric acid in concentration of one part to two of water is too strong for purposes of decoloration, a suitable action is obtained from a concentration of one part of acid to four

or five of water. If the tint is not all discharged by this treatment, wash the specimen in alcohol until it is clear, and then stain in methyl-blue as a contrast color. These two tints seem to give the best results for general purposes, though some other combinations are excellent for certain special objects. The violet and brown combination is not so easy of study to the average eye as those just mentioned; though to a skilled observer a single bacillus is more clearly defined for purpose of positive and difficult diagnosis.

Dr. Gannett said that he had examined sputa from a patient under the care of Dr. H. I. Bowditch, in which were numerous bacilli, and a very guarded and doubtful prognosis was given, but the patient has since made a perfect and apparently lasting recovery from the tubercular, or at least from the bacillary disease. . . . It is manifestly wrong to draw positive conclusions from the number of bacillary organisms found in the sputum. The examination of the sputum is very important, but it is to be regarded only as another means of judging the patient's condition, and not as a positive and absolute foundation for prognosis.

Dr. Edes asked the number of specimens it is necessary to examine in order to form an accurate diagnosis?

Dr. Ernst said that it might often be necessary to refer difficult cases to an expert in the study of bacilliary organisms. The absence of bacilli under a Hartnack microscope, without substage accessory illumination is not conclusive as to the presence or absence of bacilli.

The chairman asked if Dr. Ernst wishes to be understood as expressing the opinion that the activity of the disease, or its degree of danger and rapidity cannot be accurately judged by the number of bacilli detected in the sputum?

Dr. Ernst replied that this is precisely the opinion he now holds upon this important point. He does not consider it possible to judge the activity of the disease or its extent, or the probabilities for the patient with any degree of certainty from the number of bacilli observed in the expectoration.

Dr. C. E. Wing, of Jamaica Plain, then gave a narrative account of a trip through the greater part of North Carolina during the past summer. He said that the journey took him through the section of country which was the seat of an epidemic of severe character, which raged extensively and was of almost universally fatal character.

The region invaded by the disease is in a section of country near Statesville, and extended far into the surrounding districts. The centre of the epidemic was about one hundred miles from the mountains. The chief symptom was a flux, or as we should say, a profuse and persisting diarrhœa, which exhausted the strength of the patient, and usually resisted all treatment which had been instituted, and generally proved fatal in a very few days. Dr. Wing's observation of the disease commenced by a call to the brother of a prominent citizen of the town, a store-keeper, who was widely known, and had already suffered from dysentery for some weeks at the time of Dr. Wing's first visit. The previous treatment of the case had embraced almost every therapeutic agent known to medical science, and the great wonder to Dr. Wing's mind was, that the patient had survived the treatment, even if the powers of the system had been able to combat the disease.

Throughout this entire district of country, the people have the most implicit belief in the efficacy of turpentine, employed in large doses internally. They take it in large amounts, repeat the dose at frequent intervals, and consider the remedy as applicable to all kinds of maladies. If the turpentine alone is not sufficient to effect a cure, they are accustomed to repeat the same dose, with the added influence of a liberal portion of castor oil. This is also repeated, if the first dose is not followed by an amelioration of the symptoms. The patient to whom Dr. Wing was called had taken this combination every four hours, for some days. Dr. Wing suggested a trial of opium, as the former treatment had not been followed by any good effect. The suggestion was not, however, regarded kindly by the attending physician, who seemed to fear some fatal accident from any change of medication. He stated that if the patient should unfortunately die, the surviving friends would "be down" on the doctor. As all the cases, however, had died up to this time, and this patient also gave unmistakable indications of a gradual tendency to follow the example set by a long list of former respectable patients of the same physician, the change to an anodyne treatment was urged, and finally adopted.

This case recovered, and the extensive circle of friends and acquaintances of the distinguished patient were soon aware that the treatment formerly followed had been changed not only without detriment, but with positively beneficial results. From this time Dr. Wing's services were in constant demand, and he had some difficulty in explaining to importunate patients that he had no desire to practise, and that they must employ their ordinary medical adviser. One man came to implore Dr. Wing's services in the case of his daughter, who said that both turpentine alone, and in combination with castor oil, had been faithfully tried, but with no good result, and the father feared she must die. In this gloomy view Dr. Wing fully coincided, but the father wished that one more effort might be made to save his child's life. At length Dr. Wing gave the father a quantity of tincture of opium and a lump of tannic acid, which had become moistened on the journey was transformed into a solid mass. The treatment was followed by marked improvement, and the father came again after some days, to obtain another "hunk" of that new medicine. From that time, the treatment by tannin and opium was followed in this place, and no more fatal results are known to have occurred. To show how thoughtless the people are in the most essential measures for the care of the sick, the following case was related: Painter John was sick, and Dr. Wing saw him and gave him a "hunk" of the medicine, with careful directions as to a restricted diet. He got no better, and on making inquiries, it was learned that he had taken large quantities of water, string-beans, watermelon, and sheep. There is reason to fear that the old treatment by turpentine and castor oil has been again resumed since Dr. Wing's return.

Great value is placed upon certain indigenous herbs, which are estimated from somewhat different points of view than is customary in other parts. Thus an old and intelligent citizen designated a low plant by its local name, and descanted upon its great usefulness for cattle, assuring his auditors that this plant would surely kill or cure. He had tried it on a calf, and the animal was dead in fifteen minutes, so that he knew the plant possessed rare virtues.

DR. GANNETT asked the character of the urine in the cases treated by turpentine. A case had recently died in the hospital, in which acute nephritis had been caused by the inordinate use of turpentine.

DR. OTIS asked the character of the food, to which Dr. Wing replied that it was simply damnable.

The Secretary exhibited a number of the later additions to the list of synthetical and other drugs, and described in a few words, their most prominent characteristics.

Among those shown were Lanoline, the oily matter found in the fleece-wool of sheep. This is recommended as a valuable basis for ointments, as it seems to possess the property of passing easily through the skin, and thus forms a valuable means of securing the immediate therapeutical effect of the medicinal substance by inunction. Iodol, the reputed rival of iodoform as a disinfectant, said to contain ninety per cent. of iodone, is a grayish powder, but the speaker was unable to express an opinion of its value, as he had not yet employed it. Hypnone, the new hypnotic, obtained by the distillation of the acetate of calcium with the benzoate of calcium, is a limpid fluid, which is said to possess true hypnotic powers, without any unpleasant after-effects. It is probably yet too early to assert definitely what the full effect of this new drug may be. If the first impression in regard to its action should prove to be true, it will form a valuable addition to our resources in anodyne medication. Terebine and terpine are two derivatives obtained by the fractional distillation of turpentine, which are thought to possess a special tendency to relieve inflammatory conditions of the bronchial mucous membranes, as well as to act in the way peculiar to turpentine upon the renal organs. Two samples of iodoform were shown, in which the offensive odor of this valuable disinfectant was quite removed, and the substance rendered acceptable to the most delicate nostril by the addition of four per cent. of koumarin to the iodoform. This combination seems to possess all the disinfectant properties of the iodoform, and is a most acceptable mode of antiseptic dressing or disinfectant application.

DR. REYNOLDS said he was highly pleased to see a preparation of this drug which could be employed without the presence of the unpleasant and penetrating odor of the iodoform. This substance is now recognized as a valuable dressing, but its smell often prevents its use in proper cases.

The Secretary also showed a new "hospital inhaler," for which certain marked advantages are claimed. It is of earthen or pottery ware, and has a capacity of about one liter. The vessel is filled to a certain height with hot water (about 140°), and the medicinal substance is added. These are composed of the various volatile drugs, the vapor of which is inhaled through an appropriate mouth-piece. There is also a thermometer with the instrument, which is kept in a tube communicating with the contents of the vessel, so that the temperature may be kept at a uniform standard. The chief additional recommendation for this form of inhaler is that the temperature is preserved at a high point for a long time, owing to the material of which the instrument is made, and that the inhaler is not attacked by any of the substances which may be employed.

The Section then adjourned to the hall above, where a simple collation had been provided, to which ample justice was done.

Recent Literature.

Practical Human Anatomy; a Working Guide for Students of Medicine and a Ready Reference for Surgeons and Physicians. By FANEUIL D. WEISSE, M.D., Emeritus Professor of Surgery and Surgical Anatomy, Medical Department of the University of the City of New York, etc. New York: Wm. Wood & Co. 1886.

The book before us is evidently the work of an eminently practical anatomist who by long experience knows well what he wants to show and how to show it. The directions for exposing successive layers are admirable in their simplicity. At the beginning of the account of each region the preliminary incisions are shown on wood-cuts. The structures of each layer are concisely described and the descriptions illustrated by full series of excellent plates. Black lines in the plates show where many of the structures should be cut in the progress of the dissection, and full directions are given in special paragraphs. The idea is a good one, and it is well carried out. It seems to us that the regions exposed at once are too large. It is recommended, for instance, to reflect the skin of the chest and upper arm at the same time. It may be that this plan was adopted to avoid doubling the number of plates, already very large, and it will be possible for the student to use the book with profit while working on smaller areas. We are at a loss to see why the posterior aspect of the lower extremity should be dissected in the reverse order, that is to say, beginning with the sole of the foot.

We think the author has, except on one point, shown great discretion in what he has omitted. Superficial attempts at histology mar books intended for the dissecting room. We are glad that the subject is wholly ignored. We agree that the study of the eyeball and of the auditory apparatus does not come within the scope of the work. We agree also that it was wise to omit all applied anatomy, but we feel that the topography of the thoracic and abdominal organs deserves more notice than it has received. The only error that we have observed is the description of the *parieto-occipital* fissure, in which it is taught that it runs on the convexity of the brain from the longitudinal fissure to the inferior border. In fact, though very deep on the median surface, this fissure runs but a very short distance on the convexity, so as often to be hardly recognizable when seen from above. Perhaps the cause of this error is to be found in a similar one in Gray, Fig. 376, page 625, to which, we believe, we have already called attention.

The text is very clear and concise. We must protest, however, against the constantly recurring verb to "section" for which we know no authority, and which is in no way better than "to cut." The plates are 221 in number, almost all drawn from nature, and deserve great praise. The series showing the layers of the perineum is very satisfactory. We congratulate Dr. Weisse on the success of his work, which we believe will be a favorite with students. T. D.

— The Hospital Cottages for children, at Baldwinville, Mass., are to erect a building this spring, for the care and treatment of epileptic children. It is to be completed in June, and will accommodate thirty-five patients.

Medical and Surgical Journal.

THURSDAY, MARCH 25, 1886.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly, by CUPPLES, UPHAM & CO., *Boston. Price, 15 cents a number; $5.00 a year, including postage, to subscribers in the United States and Canadas. Foreign subscribers are charged the postage in addition.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter.

CUPPLES, UPHAM & COMPANY,
283 WASHINGTON STREET, BOSTON, MASS.

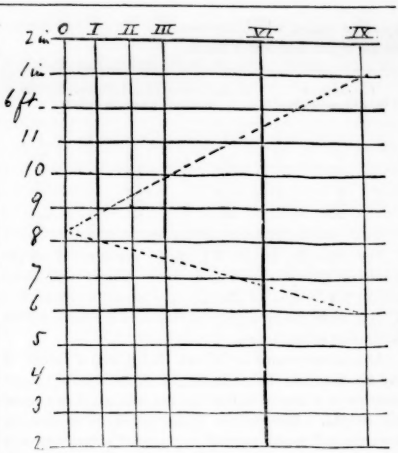
HEREDITARY STATURE.

AT the meeting last Autumn, of the British Association for the advancement of science at Aberdeen, Mr. Francis Galton, the president of the Anthropological Section, based his address upon a portion of the subject of Hereditary Stature. Since that time he has extended his inquiries and reached certain conclusions which he has laid before the Royal Society and which will soon appear in full in its proceedings. Meantime in his presidential address to the Anthropological Institute on January 26, Mr. Galton stated in a more popular form the results of his observation. This address is contained in a recent number of *Nature*.

The problem, while relating primarily to the subject of stature, is, he believes, representative of other and more important qualities. But even when restricted to the field of physical height it is a question of interest. The question substantially is this: given a group of men of the same stature, whatever it may be, required to predict as to their brothers, sons, nephews and grandchildren respectively; *first*, what will be their average height? *secondly*, what percentage of those kinsman will be of stature ranging between any two given figures? But whatever is statistically *certain* in an average based on a large number of cases, is *probable* in any given case. Hence we may judge of the probable average height of the kinsmen in the various degrees just specified of any individual of given height.

The results of a large number of observations carefully corrected have enabled Mr. Galton to give a simple, and as he claims, a complete solution of this problem. This solution is most readily shown by the following diagram, which is drawn on a scale of one-quarter that which he suggests.

The horizontal lines represent feet and inches, the average height of the race being indicated at the point of five feet, eight and one-quarter inches. The vertical lines are drawn, as shown by the numerals at the tops, at one, two, three, six and nine units from the zero line. Now let the height of any given man be marked on the line IX, as for instance, at six feet one



inch, or at five feet six inches. Let a line be drawn from the given point on IX to the normal average point on 0, cutting the other vertical lines. Then will the intersection of that line with VI indicate the probable average height of the brothers of the individual in question. Its intersection with III, the height of his sons; with II, that of his nephews; with I, that of his grandchildren. The same line indicates the stature of the male kinsman in the converse direction. VI, that of brothers, obviously; III, of father; II, of uncles; I, of grandfather.

The *regressive* tendency in all the kinsmen toward the average height of sixty-eight and one-fourth inches is thus vividly shown, the ratio of regression being one-ninth in grandchildren, one-third in children and two-thirds in brothers. It is somewhat remarkable that just this latter ratio also obtains between the "mid-parent" and the son; the "mid-parental" height being an average of two statures: (1) the height of the father, (2) the transmuted height of the mother. We may mention here that it has been found by Mr. Galton that the stature of kinswomen may be transmuted to that of their male equivalents by multiplying the height of the women in inches by 1.08.

The variability above and below the mean is shown by the graphic method as follows:—If the diagram given above be produced in its full scale (one inch between the horizontal lines) the limits of variability in any given case may be shown as follows. A set of four scales is prepared, one for each of the vertical lines. These scales are to be applied on their respective vertical lines both upward and downward from the point of intersection with the movable dotted line and the respective per cents. indicated by the scale of all individuals in the given degree of kinship will fall within the specified number of inches above and below the mean.

The following table shows the divisions on the re-

spective scales, which are accurate except for the extreme upper and lower limits.

Per cents. of included statures.	Divisions upwards and downwards from centre of scales, in inches.		
	VI.	III.	II. & I.
10	0.5	0.6	0.6
20	1.0	1.3	1.3
30	1.6	2.0	2.1
40	2.4	3.0	3.1
45	3.1	3.9	4.0
49.5	4.8	6.1	6.3

For example, in line VI, eighty per cent. of all the brothers (forty above and forty below) will come within 2.4 inches of the average mean, while on line I, (grandchildren) eighty per cent. will come within 3.1 inches of the mean.

As a consequence it follows that, given a father of say six feet five inches in height, there are only seven chances in a thousand that his son will equal or exceed his height. But as the father's height diminishes towards and to the normal average of sixty-eight and one-quarter inches the chance of a son exceeding it increase towards and to a maximum of fifty per cent.

These views are applicable to other inherited traits besides stature. Mr. Galton (as is well known) has believed for a long time that intellectual men select, as a rule, wives of more than average ability, so that the average regression of the son of a gifted man would be less than one-third. Applying this principle to the consideration of a hypothetical problem, namely, the basis of qualification in a proposed hereditary body from which a legislative upper house is to be elected, he suggests that the hereditary qualifications should not be transmitted to an indefinite posterity but should lapse after the grandchildren of the ennobled person; that all the sons and daughters should stand on an equal footing as to the transmission of the hereditary qualifications; that brothers and sisters and the descendants of these should possess the hereditary qualifications, nephews, for instance, being twice as near of kin as grandsons and possessing twice the reversion-ratio of the latter.

THE SIGNING OF PETITIONS.

WE are told that a gentleman in a neighboring State, desiring to illustrate to himself and to others the value of petitions, prepared one for the summary hanging of two individuals and got many signatures to it, including the names of the two persons whose suspension by the neck was asked for. We are quite prepared to believe the story and venture the opinion that the signers were clergymen and doctors.

The Banning petition can hardly have been forgotten in this community, and yet another has appeared on the scene equally unwise, although it is too early to speak of the comparative harm done by the two. The petition in question respectfully suggested and urged upon the Boston Board of Health "the necessity for maintaining the present regulations regarding the admission of old rags." The petition was carried about by the treasurer of a company pecuniarily interested that the present regulations should be maintained, and a prominent lawyer was employed (by whom we know not) to represent the eminent petitioning doctors.

A commission of six expert physicians, appointed by the Board of Health, had unanimously declared against the present regulations, and there was upon the petition a conspicuous absence of the names of those physicians whose opinions would naturally be asked in questions regarding the public health. These points, however, we will pass over for the present. The fact to which we now wish to call attention is that, as we are credibly informed, a large portion of the gentlemen giving the weight of their names to the petition apparently did so because the bearer of it was a gentleman and a good fellow, and did not, at the time of signing it, know what the existing regulations are; or, in other words, these gentlemen did not know for what they were petitioning, and were without the guarantee, in all cases, even as to who the bearer of the petition was — a curious psychological phenomenon which we commend to the notice of the Society for Psychical Research.

SANITATION IN WORKSHOPS AND FACTORIES.

THE increased attention which is being demanded by and paid to the rights of labor at the present time should reasonably be extended to a field of which little is known by the laborers themselves, but wherein important interests are at stake for them, as in some of the more obvious and perhaps more tangible ameliorations of their lot for which they are contending. We refer to protection of those employed in workshops and factories against the neglect or violation of sanitary precautions on the part of the employers. Mr. Gerhard, C. E., of New York, has recently published an article in *Mechanics* in which some of those remediable dangers are referred to. He speaks of the ordinary injurious trades, involving work in poisonous chemical compounds, in extremes of heat and cold, in exposure to dangerous machinery, etc. Here, of course, the danger cannot be wholly removed and men should so understand it. By the appointment of skilled inspectors, however, it can be seen that all available precautions are taken by the employers. Dangerous parts of machinery can be guarded by railings and wire nettings. Workrooms may be inspected with reference to the ventilation, warming, etc. The number and conditions of water-closets and urinals is a matter that will admit of more careful overlooking in many of the large factories, though the foul condition sometimes existing is doubtless due to the carelessness of the workmen themselves. Still, the innocent should not be made to suffer for the hygienic sins of the guilty.

The securing of good drinking water, facilities for

escape in case of fire, precautions against explosions, safeguards in the use of elevators, the protection of surrounding air or water from pollution by noxious chemical vapors or poisons — these and many other subjects would be legitimate work for a hygienic inspector who might be appointed by the State in the interest of the employed, but whom it might also be worth the while of the manufacturer himself to pay, as a measure of self interest as well as of humanity.

MEDICAL NOTES.

— The *Therapeutic Gazette*, speaking of the proper spelling of antipyrin, says that as an alkaloid it deserves the termination "ine," but on the other hand, as an acid that termination is repulsive to its nature. In this dilemma, it favors following the authority of its discoverer, who when he patented it, named it antipyrin. A parent surely has a right to the naming of his child. The German journals as a rule, spell it without the e, but most of the English and American add the final letter.

— The Duchess of Connaught, who on a former occasion was confined at Bagshot Park, experienced symptoms of septic poisoning which caused her medical attendants considerable anxiety and induced them to have her removed very soon after the confinement to Winsor castle, the risk of transportation being considered less than that of remaining at Bagshot. A subsequent examination showed the drains of the latter house to be defective. In spite of a careful repair of these drains it has been decided to have her go again to Windsor to undergo an approaching confinement.

— Dr. H. C. Wood, in a recent clinical lecture on monomania, speaking of the relation between genius and this form of insanity, says: "One of the best examples of the relation between great imaginative power and monomania is John Bunyan, the author of 'The Pilgrim's Progress,' which, according to any standard that we have a right to set up, is one of the five or six greatest books in the English language. It is certainly more read than any other book, with the exception of the Bible. No one who reads the history of Bunyan's life can doubt for a moment that he suffered from monomania with depressing delusions. He, however, finally recovered."

— M. Bedoin stated to the Belgian Royal Academy of Medicine, according to the *London Medical Record*, that he believes he has found a simple, portable, inexpensive, antiseptic method of dressing wounds suitable for the wounded on battle-fields. He recommends the unglazed paper used for filtration. This is disinfected by being placed on a stove at 120° C. (248 F.), and immediately afterwards steeped in an antiseptic substance, then slowly dried. Seven or eight sheets of the filter paper are superposed on the surface of the wound, and then lightly bandaged. This dressing weighs about forty grammes, so that every soldier can carry one in his knapsack.

— The Philadelphia Polyclinic and College for Graduates in Medicine has established a hospital for operative and other cases at the College building, Broad and Lombard Streets, Philadelphia. A number of ward patients have already been treated in the new hospital.

— The *Medical Press and Circular* gives, on the authority of a private letter from Port Elizabeth, an account of a man, who, while bathing from off a pier projecting eight hundred yards into the sea, had his leg bitten off by a shark just below the knee, but who apparently lost hardly a drop of blood in the terrible struggle that took place. The laceration caused by the jagged teeth and the hæmostatic action of the salt water, are referred to as causes of the slight hæmorrhage. Amputation above the knee was forthwith performed, and a good result obtained.

— Dr. W. Thornton Parker, of Newport, R. I., from his experience on the Western prairies, considers the bite of the skunk more to be dreaded than that of the rattlesnake. He says hydrophobia exists to a considerable extent among these pests. He has known several cases where the skunk has invaded tents and corn-houses, and inflicted bites not always in anger, but in searching for food, and thus gnawing the hands or face of sleepers. He does not say that under the latter circumstances hydrophobia is communicated, but says there is a general impression that the skunk's bite is dangerous, and believes that the danger is usually from hydrophobia.

— An old member of the medical profession in Chicago tells the *News*, of that city, a story which he says, Dr. J. Adams Allen told him many years ago. Dr. Allen, as the story goes, was just beginning his practice when, one winter day, seated in a car, muffled to the ears, he overheard the following conversation between two passengers who were sitting where they could not see his face — "Say, George," said one, "what kind of a doctor is this young Allen?" "All I know about him is that he snatched my aunt from the grave last summer, that is, I shall always think he did." "Did he, indeed?" said the other; "well, he must be a pretty good doctor then. What was the matter with your aunt?" "Oh, she was dead and buried, you know."

— As to just what sort of a surgical operation has recently been performed on Lieutenant Greely, of Arctic fame, we are in ignorance, but whatever it was, he is much more to be pitied for having to undergo it in the daily papers than upon the operating table. We are told that he "has had the nerves at the base of the spine severed, and the flesh and muscles separated — a severe surgical operation." Any operation which involves the separation of the flesh and muscles must indeed be severe; and to one who has suffered this radical dissection, the "searing of the spine with a red-hot iron, similar to the operation which —— —— underwent in Paris a few years ago," and which appeals to the reportorial mind as the acme of horror, must appear as really a rather tame proceeding.

— A correspondent of the *Medical and Surgical Reporter*, writing apropos of a paper read at the late meeting of the New York Medical Society, by Dr. Hamlin, of Auburn, on "Emission of Semen as a Means of Diagnosis of Death by Hanging," says that he has had opportunity of verifying Dr. Hamlin's observations. At Fort Smith, Ark., there are hung annually, a dozen or more criminals, and in every instance there has been emission. The late Dr. J. E. Bennett called attention to it in 1880, and the writer's observations extend from that to the present. Dr. Bennett, who was United States jail physician at that time, and many years previously, said that he never knew a case of hanging in which the emission was not present, and as a means of diagnosis of death, it was certain.

— If contributors who sometimes, and not without reason, feel aggrieved at the occasional typographical errors in their articles which will contrive to elude observation, could see some of the threatened disasters of that nature from which they are mercifully delivered, their feelings would be merged in one of deep thanksgiving. For instance, a gentleman held in the highest esteem by his contemporaries, professional and social, made the remark before a medical society, that "he had himself at one time considered cirrhosis the usual result of excessive alcoholic indulgence," which was printed "he had himself, at one time, considerable cirrhosis, the usual result," etc. Equally narrow was the escape of the gentleman whose remarks on the "Etiology of Rabies" were in the proof perverted to the Etiology of "Babies."

BOSTON.

— The Bill for separating the Massachusetts Board of Health from Lunacy and Charity has become a law.

— Governor Robinson has also signed the bill prohibiting the sale or gift of tobacco to boys under the age of sixteen.

— The health of the "flooded district" is not injuriously affected. The number of cases of typhoid fever reported from this locality since January is four — not more than last year, and the health of the entire city is as good as at the corresponding time last year.

— Mrs. Clara T. Leonard, of Springfield, who was appointed to the State Board of Health, Lunacy and Charity by Governor Long in 1880, and has served ever since, has sent in her resignation to the Governor, on account of ill health. Her term of service would regularly have expired June 7, 1890.

— Within the last fortnight, two hearings have been held by the Committee on Health of the City Government, on a petition by the paper manufacturers for the abrogation of the present requirement of the local Board of Health for the disinfection of rags brought to this port. The contract for disinfection is held by the Boston Disinfecting Company, which charges five dollars per ton for fumigating the rags. This expense, and the trouble otherwise caused by the regulation has, the petitioners claim, led manufacturers to land most of their rags at other ports where consular certificates from the ports of shipment are accepted as evidence of the safety of the rags.

— An evening dispensary at St. Andrew's Church, 27 Chambers Street, has been established under the charitable auspices of Trinity Church, for the benefit of the many workingwomen who, reluctant to lose their half-day's pay, or to incur the displeasure of their employer by absence, neglect their health and become seriously ill, when the advice of a physician might save them many days of suffering. It is under the charge of two female physicians, both members of the Massachusetts Medical Society, and earnestly interested in the welfare of working girls. At present, the Dispensary is to be open Tuesday and Friday evenings, and it is thought that other evenings may be required to be added later.

NEW YORK.

— Two brothers, candy dealers on Chambers Street, have each been fined $100 for selling "rock and rye" drops, which on analysis by Prof. Elwin Waller, of the Health Board, were found to contain fusel oil.

The Trustees of the College of the City of New York have appointed William Stratford, M.D., Ph.D., to the chair of Professor of Natural History, Physiology and Hygiene, made vacant by the death of the late Dr. John C. Draper.

— The twenty-fifth annual commencement of Bellevue Hospital Medical College was held on the evening of March 15th, in the Carnegie Laboratory, which was elaborately draped in mourning in consequence of the death of Professor Austin Flint. The degree of M.D., was conferred upon one hundred and thirty-nine graduates, by the president, Dr. Isaac E. Taylor, and the address to the class was made by Dr. John C. Dalton, President of the College of Physicians and Surgeons, who in it paid a most touching and eloquent tribute to the memory of Dr. Flint.

— The funeral services of Dr. Vanderpoel were held at his late residence in 39th Street on the afternoon of March 15th, and was largely attended by the profession. Among the pall-bearers were Drs. Alfred L. Loomis, C. R. Agnew, John C. Dalton, Fordyce Barker, C. F. Chandler, D. B. St. John Roosa, and Albert Vander Veer, of Albany. On the morning of the funeral a special meeting of the Charity Organization Society, for the formulating of whose constitution Dr. Vanderpoel was one of the citizens selected by the State Board of Charities, was held for the purpose of taking action in regard to his death.

— The funeral of Dr. Flint was held on Tuesday, March 16th, at Christ Church, in which gathered an immense number of physicians, including all the most noted men of the profession in New York, as well as a number from various other cities. The services were very simple, and there were no pall-bearers. On Sunday, the day following his death, special meetings of

the Faculty of Bellevue College and of the Executive Committee of the New York County Medical Association were held, at which appropriate resolutions in regard to the sad event were adopted. At the meeting of the Academy of Medicine held March 18th, the President, Dr. A. Jacobi, announced that he would himself claim the privilege of pronouncing before the Academy the eulogy of his illustrious predecessor in the office.

—The Hospital Saturday and Sunday Association met in the Mayor's office on March 18th, and made the following distribution of the undesignated contributions received in aid of the institutions belonging to the Association :—

Mount Sinai Hospital	$5,013.80
St. Luke's Hospital	3,693.26
Society for the Relief of the Ruptured and Crippled	3,586.86
German Hospital	3,385.87
Presbyterian Hospital	1,659.82
St. Mary's Free Hospital for Children	1,283.49
Woman's Hospital of the State of New York	1,208.01
House of Rest for Consumptives	1,072 27
Home for Incurables	1,035 64
Home of the Holy Comforter	1,051.47
New York Infirmary for Women and Children	843.75
New York Orthopædic Hospital	770.26
New York Eye and Ear Infirmary	775.34
French Hospital	755 76
Hahnemann Hospital	659.98
Manhattan Eye and Ear Hospital	611.78
New York Ophthalmic Institute	636.82
New York College and Hospital for Women	537.34
Ophthalmic and Aural Institution	499.53
New York Skin and Cancer Hospital	496 03
Home for Convalescents	425.09

Miscellany.

A CASE OF PERFORATING ULCER OF THE STOMACH, OPENING INTO THE LEFT VENTRICLE OF THE HEART, AND CAUSING DEATH BY HÆMORRHAGE.

At the meeting of the Pathological Section of the Academy of Medicine, reported in the *Medical Press and Circular* (March 3, 1886), Dr. Finny exhibited an extremely rare specimen of an oval ulcer (1 by ½ in.) of the stomach, situated on its anterior wall two and a half inches from the cardiac, and two from the lesser curvature, leading up to and perforating the heart. The floor of the ulcer was the muscular structure of the under surface of the left ventricle, about one inch from the apex; and the ulcer, after perforating the stomach, had eaten through the diaphragm and the pericardium. The stomach was adherent to the diaphragm through the ulcer, but the adhesions were very slight, and of recent date. The pericardial sac had been obliterated by adhesive inflammation, and over the whole of the left ventricle the adhesions were very dense. Through the larger of several interstices, between the exposed muscular tissue of the apex, a probe could be passed upwards, and was found to enter the left ventricle behind a musculus papillaris attached to the posterior mitral curtain. The patient from whom the morbid specimen was removed had died of syncope on December 9th, 1885, preceded by the passage of blood from the bowels. Strange to say, there was no hæmatemesis. At the autopsy, the stomach and the whole intestinal canal were found full of liquid blood, and the stomach alone contained two quarts. The source of the blood was the left ventricle, and it is probable the blood escaped into the stomach during both systole and diastole.

The clinical history of the patient was as follows :—

A farm laborer, aged nineteen, was admitted, under Dr. Finny's care, into Sir Patrick Dun's Hospital, at the end of October, 1885, suffering from articular rheumatism of a subacute type, of a month's duration, and presenting the signs of pericarditis in the stage of lymph-exudation. In a few days the friction disappeared, while there was no subsequent effusion, and all the other symptoms of rheumatism passed away. There were no symptoms pointing to disease of the stomach, with the exception of pain referable to the sixth rib, about the usual seat of cardiac impulse, and which was also referred to the right coracoid process. This pain was stated to have been present, off and on, for nearly five years, to be of an intermitting nature, and at times of great severity. During the patient's stay in hospital there were about four such exacerbations, which required morphia for their relief. This pain was never felt in the epigastrium or back; was not induced or relieved by the introduction of food or change of posture, nor did it bring on any nausea or vomiting. From this latter symptom he never suffered, and even during the fatal bleeding there was no hæmatemesis. For seven days before death the pain had greatly abated. During the night of December 8–9, the patient had but little sleep, and in the morning, about 8 A.M., he passed blood from the bowels, and very soon after died in syncope.

The autopsy revealed the conditions described above.

The fatal steps in the pathological history of the case were: 1st, Ulcer of the stomach of unknown duration; 2d, Rheumatic pericarditis and adhesions of the left ventricle to the diaphragm, with obliteration of the sac; 3d, Recent activity in the ulcer, perforating into the muscle of the heart.

The general muscular structure of the heart under the microscope was perfectly normal, and free from fatty degeneration, except the fibres at the floor of the perforation, which were granular and broken down, though free from all fat.

Dr. Finny referred to the anatomical relations of the liver and stomach to the diaphragm, and stated, by observations made, that while, in the majority of instances, the liver, by its left lobe, entirely separates the stomach from the portion of the diaphragm to which the pericardium is applied, there are exceptional specimens where the left lobe of the liver is small and pointed, where a small triangular portion of the extreme front of the pericardial aspect exactly corresponds to the anterior wall of the stomach in the very position of the ulcer present in this case. This he further illustrated by reference to Braune's topographical plate taken from the frozen subject. Dr. Finny pointed out the extreme rarity of such cases, and when he first discovered its peculiar features, he thought it was unique inasmuch as no such specimen was to be found in the pathological museums of Dublin or London, and no record of such a case was to be met with in the Pathological Transactions, or in any of the books devoted to the subject of gastric ulcer, nor could he obtain any reference to any reported instance in the medical literature of Great Britain and Ireland.

Further research, however, showed him that it was not unique, as there are three similar cases recorded in Vienna — the first by H. Chiari in 1880, the second by F. Brenner, and the third by Oser in 1881; and each of these latter observers seemed to have been unaware of the other reported cases. He thought the fact of a chamber having been formed between the heart and the pericardium showed that probably a gastric ulcer first formed the abscess, and that it opened from the stomach, forming a smaller one underneath the diaphragm, and from thence reached the pericardium. Having regard to the slight character of the adhesion between the outer surface of the stomach and the diaphragm, he did not think that the passing of the ulcer through the diaphragm could have set up such a pericarditis as was found in the case. He thought that pericarditis was due to a rheumatic attack, which had preceded the perforation of the diaphragm by the ulcer from the stomach. Nor did he see any difficulty about the solution of the muscles of the heart by the gastric juice.

The base of the ulcer and the muscular tissue of the heart were turned into a granular *débris*, which was the result of the solution. The rest of the heart was perfectly healthy, and showed no sign of fatty degeneration whatever. Nor did he see why the heart should not have suffered from the action of the gastric juice, when they saw that the tendinous portion of the diaphragm, which opposed the progress of the ulcer, was dissolved by the gastric juice at the floor of the ulcer. Having thus gone through the diaphragm, which was of its full thickness, the gastric juice might have acted in a similar way on the muscular tissue of the heart.

RESOLUTIONS OF THE MEDICAL BOARD OF THE MASSACHUSETTS GENERAL HOSPITAL IN MEMORY OF DR. J. H. WHITTEMORE, THE LATE SUPERINTENDENT.

AT the annual meeting of the Medical Board of the Massachusetts General Hospital, the following resolutions of respect to the memory of Dr. Whittemore, the late Superintendent, were passed:

This, our annual meeting, the first meeting of the Medical Board of the Hospital since the death of Dr. James Henry Whittemore, Resident Physician and Superintendent, affords us the first opportunity of placing upon our records a tribute to his memory, in the expression of the high appreciation of the distinguished services he rendered to the Hospital, and all the varied interests committed to his charge.

He was pre-eminently a representative of the dignity, the honor, and the magnitude of so great and so charitable a trust; he brought to bear upon the executive department of this institution, sound methods, ripened judgment, and a keen, clear insight, and applied to the complex questions of immediate necessities, and prospective and more remote requirements, the happiest combinations of foresight and wisdom.

To him, especially, the Hospital owes its great reputation in this community as an effective power, working for the good of the deserving poor; and to him, more than to any other, its widespread name as the representative of the American hospital system.

Men rarely demonstrate as he did, daily in our sight, the inflexible will and the superb qualities, which enable a man to do his whole duty, so long as life lasts. Maimed and helpless, racked and torn by pain, he completed the task he had assigned himself, and dying, left no unfinished work. He needs no eulogy, for of him, also, it may justly be spoken:—"*Si monumentum quæris circumspice.*"

To the Staff and to the individual member he sustained a nearer relationship. He was our friend. The lines governing his conduct were firmly fixed, and led straight to a constant goal — duty; but no path was so well-worn, or bore such marks of his frequent footsteps, as that which led to the altar of friendship; its fires never smouldered, but burned brightly, fed by many and fresh sacrifices; for, "he who will have shown himself in all cases as regards friendship, worthy, constant, and steadfast, such a one we ought to esteem of a class of persons extremely rare — nay, almost God-like." Unswerving fidelity to duty and to friendship were his distinguishing traits.

THE PREVENTION OF MAMMARY ABSCESS.

IN a recent number of the *Therapeutic Gazette*, reference was made to the method of prevention of mammary abscess recommended by Dr. Edis, by the use of support by means of a bandage or towel. Dr. Edis appears to have used this method after every delivery, and, by beginning it before lactation was established, with assured success. Occasionally, however, one is called to cases where abscess is on the point of forming, either from neglect or injudicious treatment, and where, consequently, something more is required. Under such circumstances, Mr. Philip Miall (*British Medical Journal*, November 21, 1885,) states that he has repeatedly seen all the symptoms of a hot, heavy, inflamed breast, with redness of skin, throbbing and deep-seated pain, pulse being one hundred and twenty in the minute, all disappear in the course of a few hours under fomentation of hot water and ammonia. An ounce of carbonate of ammonia is dissolved in a pint of boiling water, and when solution is affected the temperature will scarcely be too high for fomentation with cloths dipped in the liquid. These must be assiduously applied for half an hour at least, and repeated for two or three hours if necessary. It is well to protect the nipples, though Mr. Miall states that he has never known them to be injured. Relief is immediate, and more than three applications are seldom required. According to Mr. Miall, unless applied too late or improperly, or some foolish rubbing or drawing with the breast-pump be used, this remedy may be thoroughly relied upon.

OBITUARY. AUSTIN FLINT, M.D.

DR. AUSTIN FLINT whose sudden death on the 13th inst. from apoplexy, has already been announced to our readers, was descended from an eminent medical ancestry. First in the distinguished line was Dr. Edward Flint, his great-grandfather, a physician of note in Shrewsbury, Mass.; then came Dr. Austin Flint, of Leicester, the grandfather, who was a surgeon in the Revolutionary Army; then the father, Dr. Joseph Henshaw Flint, one of the most noted physicians and surgeons that the Connecticut Valley has ever had. Dr. Austin Flint was born at Petersham in Worcester County, October 20, 1812. He studied at Amherst and Harvard, and was graduated from the University Medical School in 1833. He practised at Northampton for a time, then in Boston, and in 1836 went to Buffalo, where he was settled until 1844; he was then called to a professorship in the Rush Medical College at Chicago, which he filled for a year, returning to Buffalo, where he established the *Medical Journal*, which he continued for ten years; he was one of the founders

of the Buffalo Medical College, where he was professor until 1852; for four years thereafter he was professor in the Louisville University, and then returned to another professorship at Buffalo; for three winters from 1859 he was professor of clinical medicine in the medical school at New Orleans. In 1861 Dr. Flint made his home in New York city, where he became one of the physicians to Bellevue Hospital, and was appointed to two professorships — the principles and practice of medicine and clinical medicine at Bellevue, and pathology and practical medicine at the Long Island College Hospital. From the latter institution other duties forced him to sever his connection in 1868. In 1876 he was a delegate to the International Medical Congress at Philadelphia, where he delivered a notable address on "Medicine." During the past winter he received an invitation to deliver an address on the same subject at the coming meeting of the British Medical Association. This honor he had accepted. He attended the Congress at London in 1881 and at Copenhagen in 1884, and had been chosen president of the next Congress, to be held at Washington in 1887.

He was president of the New York Academy of Medicine in 1872 and of the American Medical Association in 1884. He was also a member of a very large number of learned societies in this country and Europe.

As an author Dr. Flint attained perhaps his widest fame. His "Treatise upon the Principles and Practice of Medicine," published in 1866, ran through seven editions. He was engaged during the past winter in revising it for another edition. The sales of this book are said to have reached nearly 40,000 copies. A work on "Clinical Study on Heart Sounds in Health and Disease," which he wrote in 1852, received the first prizes of the American Medical Association in 1852 and 1859. His work on "Phthisis," and his "Manual of Percussion, etc.," have long been standard works.

A strong constitution and perfect health had enabled Dr. Flint to keep up his active labors as teacher, writer, and practitioner to the last days of his life. The fact that his selection as president of the Medical Congress of 1887 had proved acceptable to both parties in the controversy, may make his removal another bar to the success of that undertaking — already so beset with difficulties.

Correspondence.

CO-EXISTENCE OF SCARLET-FEVER AND MEASLES.

WINDHAM, ME., March 22, 1886.

MR. EDITOR, — The case of "Co-existence of Scarlet-fever and Measles," reported in the JOURNAL of 11th inst., by Francis F. Brown, M.D., reminds me of a similar case occurring in my own practice, in the year 1875, during quite an epidemic of these eruptive fevers.

Jennie B., aged seven years, had suffered for several days before I saw her, from the usual precursory symptoms of measles, and at the time of my visit, the eruption had made its appearance on the face and chest. It was well-marked, and there was no mistaking the nature of the disease. At my next visit, twenty-four hours later, an entirely new state of affairs existed. Instead of measles, we had before us a typical case of scarlet-fever with all the accompanying symptoms.

Unlike Dr. Brown's case, the eruption of measles had disappeared, save a trace on the forehead, and a bright scarlet rash covered the entire body with all the characteristic symptoms of scarlet-fever, which continued for five or six days, and on its disappearance, the eruption of measles returned, and having had "one day out" it began to fade from the face on the third day, instead of the fourth, as is the rule. Convalescence was slow but the patient made a good recovery.

There can be no doubt as to the co-existence of the two diseases in this case, and although the measles got the start of the scarlet-fever in point of time, yet in point of intensity, the scarlatina had the better of its antagonist.

Very truly yours, B. F. DUNN, M.D.

Deaths reported 2,024: under five years of age 682; principal infectious diseases (small-pox, measles, diphtheria, and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 276, consumption 327, lung diseases 306, diphtheria and croup 121, whooping-cough 31, diarrhœal diseases 24, typhoid fever 27, cerebro-spinal meningitis 18, scarlet fever 26, malarial fever 13, erysipelas ten, puerperal fever two, small-pox two, typhoid fever one. From typhoid fever, Philadelphia nine, New York and Cincinnati six each, Lowell two, Boston, Cambridge, Lynn and Lawrence one each. From scarlet fever, Philadelphia 12, New York seven, Cincinnati four, Boston, Lowell, and Newburyport one each. From cerebro-spinal meningitis, Philadelphia six, New York four, New Orleans three, Boston, Cincinnati, Worcester, Fitchburg, and Waltham one each. From malarial fevers, New York nine, New Orleans two, Philadelphia and Nashville one each. From erysipelas, New York five, Boston two, Philadelphia, Cincinnati and Springfield one each. From puerperal fever, Philadelphia and Boston one each. From small-pox, New York two. From typhus fever, New Orleans one.

In 111 cities and towns of Massachusetts, with a population of 1,376,736 (population of the State 1,941,465), the total death-rate for the week was 17.41 against 17.35 and 14.83 for the two preceding weeks.

In the 28 greater towns of England and Wales, with an estimated population of 9,093,817, for the week ending February 27th the death-rate was 24.2. Deaths reported 4,217: infants under one year of age 932; acute diseases of the respiratory organs (London) 647, whooping-cough 161, measles 91, scarlet fever 34, diphtheria 33, fever 33, diarrhœa 32, small-pox (Liverpool) one.

The death-rates ranged from 13.1 in Derby to 30.5 in Blackburn; Birmingham 21.7; Bradford 18.1; Hull 19.6; Leeds 25.5; Leicester 17.9; Liverpool 22.6; London 25.0; Manchester 28.9; Nottingham 26.6; Sheffield 22.1; Sunderland 22.1.

In Dublin 30.4.

For the week ending February 27th in the Swiss towns, there were 34 deaths from lung diseases, consumption 33, small-pox seven, whooping-cough five, measles, scarlet fever and typhoid fever each three, puerperal fever two, diphtheria and croup one.

The death-rates were: at Zurich 24.8; Geneva 20.2; Basle 15.5; Berne 26.7.

The meteorological record for week ending March 13, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole of the United States Signal Corps. —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 13, 1886, TO MARCH 19, 1886.

HOFF, JNO. VAN R., captain and assistant surgeon. Ordered from Department California to Department Missouri. S. O. 60, A. G. O., March 15, 1886.

ROBERTSON, R. L., first lieutenant and assistant surgeon. Granted leave of absence for one month. (Fort Ringgold, Tex.) S. O. 29, Department Texas, March 8, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDING MARCH 13, 1886.

BENSON, J. A., passed assistant surgeon. Resignation accepted to take effect April 6, 1886, and leave of absence granted until that time, March 10, 1886.

CIRCULAR. REVOKING REGULATIONS ISSUED OCTOBER 1885, FOR THE MAINTENANCE OF QUARANTINE INSPECTIONS ON THE NORTHERN FRONTIER OF THE UNITED STATES.

TREASURY DEPARTMENT,
OFFICE SUPERVISING SURGEON-GENERAL,
U. S. MARINE-HOSPITAL SERVICE,
WASHINGTON, D.C., MARCH 17, 1886.

To the Medical Officers of the Marine-Hospital Service, Customs Officers, and others concerned:

Official information having been received that the small-pox which recently prevailed as an epidemic in certain provinces of the Dominion of Canada, is now under control; therefore the Regulations issued October 10, 1885, for the maintenance of quarantine inspections on the northern frontier of the United States, are hereby revoked.

JOHN B. HAMILTON,
Supervising Surgeon General.

DEATH.

Died in Roslindale, Mass., March 19, 1886, Robert Mendum Otis, M.D., M.M.S.S., aged forty-two years.

SOCIETY NOTICE.

NORFOLK DISTRICT MEDICAL SOCIETY.—A meeting for Scientific Improvement will be held at Room 7, Palladio-Hall Building, corner of Warren and Dudley Streets, Roxbury, March 30th, at 7.45 P.M. Communications: I. "A Case of Gangrene of the Lung," C. E. Stedman, M.D. The discussion will be opened by Jos. H. Streeter, M.D. II. "The Treatment of Synovitis by Aspiration and Martin's Bandage," E. P. Gerry, M.D. The discussion will be opened by Chas. F. Withington, M.D. Members of other Districts are invited to be present and participate in the discussions. S. ALLEN POTTER, M.D., *Secretary.*

APPOINTMENT.

Dr. Frederick C. Shattuck has been appointed Visiting Physician to the Massachusetts General Hospital.

A MEDIASTINAL TUMOR.

BY E. N. WHITTIER, M.D.
Visiting Physician Massachusetts General Hospital.

The condition of a patient recently under observation has suggested the topic of this paper: for the case illustrates the distinguishing features of the disease, in the obscurity of the earlier symptoms, and the etiology; later, in the evidences of rapid growth shown by external signs, and by local mechanical interference with the functions of the thoracic organs, and at last, in the conclusive proofs of extreme malignancy.

A man, forty-three years of age, of good family history, free from taint, without signs or history of rheumatism, alcoholism, syphilis, or Bright's disease; by occupation a teamster, and by this subjected to much exposure and heavy exertion, had complained for two months of attacks of difficulty in breathing: attacks of such severity, and so wholly without warning or assignable cause, that he had given up work of late. Even slight changes of position in bed, from lateral to dorsal decubitus, seemed to cause dyspnœa, and exertion of any kind was rendered difficult, and dreaded, by reason of suffocative attacks.

Further questioning brought out the fact of some obscure intra-thoracic disturbance eight years ago, disabling him for two months, and said by his physician to have been caused by some over-exertion in lifting; this, the patient insisted, had been fully recovered from, and never since, the source of any trouble whatever.

Paroxysms of coughing had been frequent of late, and an expectoration, at first mucous, white, and frothy, had become thinner, watery, and sometimes tinged with blood. Pain has not been a source of complaint, nor had there been palpitation nor the usual rational signs of cardiac disturbance; the voice had been unchanged, and there had been no swelling of extremities.

When first seen, three weeks previous to my later observations, the following additional facts were the only ones obtainable: At times, the face, and particularly its right side and the right side of the neck, seemed to enlarge, and he grew livid, dusky, and even purple; the veins were ready to burst, and his hands and feet, in fact, his whole body would be cold and wet, with clammy moisture, and there was great laboring for air, and constant expressions of apprehensions of impending death.

The physical signs in part corroborated his statements, and in addition, there was found swelling and slight œdema above the clavicles, and increased resistance to palpation, with irregularities on deep pressure, suggesting glandular enlargements. There was less expansion above and below the left clavicle than in corresponding regions on the right side during inspiration, and at the junction of the third or left costal cartilage with the sternum, a limited elevation of the surface could be seen, which transmitted to the fingers a rise and fall, synchronous with the radial pulse; well-marked dulness was found in the elevation and across the median line of the sternum, and from the left apex down to the third intercostal space; while the respiratory sounds were greatly diminished, and modified in the direction of broncho-vesicular, with some exaggeration of voice-sounds. Fine, moist râles were abundant in the remaining portion of both lungs; most marked posteriorly, but there was no pleural effusion on either side. The tumor communicated no thrill, nor was there evidence of lateral expansion, but the left radial was less than the right in force. The pupils were equal. Pulse 104, small, but regular; respiration 36 per minute. No abnormal condition other than these as described, were found.

There were good reasons for the two, and somewhat diverse opinions reached by the attending and consulting physicians at this date. The family physician, weighted with the obscurity of the earlier symptoms, assigning large influence to occupation, and previous history of traumatism, or over-strain, had given an opinion of aneurismal tumor. The consultant, examining without knowledge of this opinion, and without the fatigue and prejudice associated with the tedious uncertainty of the two preceding months, based his opinion largely upon the physical signs, and less upon the possible diagnostic influences of the history of the case.

If we carefully consider the symptoms which challenge careful consideration, we shall be led to regard as the most important of the symptomatic phenomena, those associated with disturbances of respiration. They are, in the order of their value in diagnosis, as follows: Rapid breathing; dyspnœa on exertion; dyspnœa on change of position; dyspnœa, explained by physical signs; orthopnœa; paroxysmal dyspnœa.

For the purposes of eliminative diagnosis, we need to consider more at length the causes of rapid breathing. They are:

Increase of blood	Hyperæmia Passive congestion	Pulmonary.
Increase of tissue	Fibroid-Phthisis. Tuberculosis.	
Increase of water	Œdema of lungs. Capillary Bronchitis. Pleurisy with Effusion. Pericarditis.	
Empyema.		
Tumors	Aneurismal. Mediastinal new growths. Malignant diseases of the lungs.	
Pneumothorax	Pyo- Hydro-	
Abscess.		
Gangrene.		
Asthma	Renal. Cardiac.	
Anæmia.		
Disease of Pneumogastric.		

The rules of eliminative diagnosis enable us to throw out as not material to the present discussion, all of the foregoing, excepting œdema of lungs, laryngeal paralysis, and the varieties of tumors embraced under the term mediastinal new growths and aneurismal.

Pressure upon, or disease of, the pneumogastric, caused by enlarged cervical or bronchial glands, intra-thoracic new growths and aneurism, is recognized as an important agent in the production of rapid breathing. The history of this case may be confidently appealed to in confirmation of the existence of one or more of the above causes.

The pulmonary œdema, joined, as it is, with evidences of venous stasis in the face and neck, cannot be wholly referable to influences exerted upon the pneumogastric, and it is only explainable by hindrances to return of blood through the superior vena cava, by causes existing within the thoracic cavity.

I quote the admirable words of Bruen: "When we consider that in the diagnosis of aneurism of the aorta, every sign and symptom has in turn been found to be fallacious in the ever-varying conditions under which aneurisms appear, and that one is forced to say that aneurism has no pathognomonic signs or symptoms, the

difficulties in the way of differential diagnosis of intra-thoracic tumors may be recognized. Moreover, the diversity in the peculiarities of each case, the multifarious character of the pressure symptoms and physical signs, and the absence of a precise order of phenomena peculiar to tumors in this situation, may render a positive diagnosis in the early stages very difficult."

In this case, there had been none of the causes predisposing to disease of the coats of the arteries, but there was offsetting this, the history of laborious occupation, of violent exercise, and of obscure traumatism of seven or eight years previously; pain was nearly absent; this, too, in spite of the evidences of a tumor, as shown by the limited prominence in the left sternal region; pulsation and thrill, murmur, and lateral expansion were absent, important diagnostic factors in aneurismal growths, and the recurrent laryngeal gave no direct sign of involvement, neither hoarseness nor aphonia having existed. The variation in the radials implied obstruction, or pressure from some one of several intra-thoracic causes, not from aneurism alone.

Mediastinal new growths, the majority of which are lympho-sarcomatous, oppose in their earlier stages many obstacles to a conclusive diagnosis. Broadly stated, there are no symptoms or physical signs, nor any precise order of phenomena peculiar to, or definitely diagnostic of intra-thoracic new growths.

The wider the departure from the usual concurrent signs of intra-thoracic tumors; the more diffused the signs of obstruction, and of disturbed mechanism referable to the mediastinum (when thoughtfully considered in connection with the history of the case) the firmer the foundation upon which to rest a diagnosis, of the class of intra-thoracic new growths of which one case is typical.

We were, in considering this case, mindful of the fact, that these growths increase from without inwards, that the slight external tumor might be but a surface indication of extensive deposits, an opinion confirmed by the large area of percussion dulness: that the physical signs of collapse of pulmonary lobules, upper left front, and the evidence of venous stasis in face and neck were conjoint witnesses inseparably connected and associated with the cervical glandular enlargements, an aggregation unimpeachable and conclusive.

Let us now turn to the consideration of the later symptoms found in the rapid growth of the tumor, and in the evidences of obstruction, declared by the external signs, and the local mechanical interference with the functions of the thoracic organs.

At an interval of four weeks the following conditions existed: —

The face, neck and left arm were œdematous and dusky: the neck broadening to its base was much enlarged, irregular in surface, and the supra-clavicular depressions were obliterated; anteriorily, from the sternal notch upwards, the growth masked the outlines of the larynx. Respiratory movements in the left upper chest were absent; the heart's apex was displaced downwards and outwards into the seventh interspace, outside the nipple line; to rapid breathing, there had been added orthopnœa, of the most pronounced type, the patient sleeping much of the time with his head bending forward towards his drawn-up knees.

The tumor before noted as a small elevation had so increased in size as to involve the costal cartilages and the ends of the second, third and fourth ribs, and measured three and one-half by four and one-half inches, with an estimated elevation of one and three-fourth inches; it was a firm, resisting, non-heaving, non-expanding mass, free from pain and not tender on palpation or percussion; there was flatness on percussion, from the left apex to the third interspace and thence to the right of the sternum. Vocal fremitus was absent in this region; respiratory murmur other than transmitted could not be heard; the voice sounds were not distinctive; urgent symptoms, referable to obstruction of the trachea, as well as of the superior vena cava, became more constant, and Dr. Porter's opinion was sought, with reference to surgical measures to secure relief. He decided that the growth in front of the larynx and the evidence of obstruction beneath the sternum precluded tracheotomy, and rendered any operation impracticable.

The evidences of extreme malignancy were found in the processes destructive to life, and rapidly advancing during the few days previous to the death of the patient. Briefly these proofs were, glandular enlargements, cervical and axillary, particularly on the left side, causing obstruction and so great increase in size of the left arm that it was nearly twice the size of its fellow; cyanosis of the face and neck, taking the place of the previous lividity and dusky hue; persistent dilatation of the superficial veins of the neck and face; pressure signs referable to the trachea and left primary bronchi, and in the condition of the heart, displaced downwards and outwards, with marked signs of cardiac failure; most significant of all, a tumor, increasing rapidly along the lines of least resistance, and involving, while not destroying, a portion of the anterior chest wall. We easily recognize in these physical signs the classical phenomena of obstruction, from a quickly developing intra-thoracic new growth.

The rational and physical signs accompanying mediastinal tumors, are complex and varying, and modified as such signs must be by reason of the changed anatomical relations of the structures involved, and the inconstant position of new growths in this region; careful consideration will, nevertheless, reveal the co-existence and close association of diagnostic factors of these three classes, namely, disorders of circulation, disturbances of innervation, respiratory phenomena.

IMPERFORATE HYMEN WITH RETENTION OF THE MENSTRUAL FLUX.[1]

BY W. H. BAKER, M.D.

FROM the fact that in the practice of gynæcology for twelve years past I have met with but one case, the report of which I wish to present to you this evening, assures me that as a class, they are infrequent.

We often see cases where there is more or less complete atresia of some part of the vaginal canal, as a result of a severe labor, or following some sloughing of the parts after some of the exhausting fevers; but a complete closure of the outlet of the vagina from a congenital malformation, with a well-formed vagina, uterus, and ovaries, occasioning a distention of either the vagina, uterus, or Fallopian tubes, or of all, is of much more rare occurrence.

The report of the case is as follows: Mrs. A. L. was referred to me by Dr. Towne, of Manchester, N.

[1] Read before the Obstetrical Society of Boston, February 13, 1886.

H., who had made the above diagnosis, and desired me to operate. She was a Swede, twenty-one years of age, and had been married six months. From the age of fourteen, she had molimina of menstruation, but there had never been any flow. These symptoms varied in intensity, and consisted of pain in the groins, feeling of fulness, and weight in the lower abdomen, sometimes so severe as to render her unconscious for a time. Since her marriage there had been frequent attempts at intercourse, accompanied with pain on her part, and but little satisfaction on the part of her husband. Her general health appeared to be good.

Physical examination showed the external organs of generation well developed, with the exception that the hymen was imperforate, and the meatus urinarius was so much enlarged that it readily admitted the fore-finger. It, however, occasioned no incontinence of urine; this latter I also considered a fault of development, rather than a dilatation from the unsuccessful attempts at coition. With one finger in the rectum and one in the bladder, an indistinctly-fluctuating tumor was found to nearly fill the pelvis. By recto-abdominal palpation, no evidence of a distention of the uterus or tubes could be established.

June 24th, 1885. The patient being etherized, and a more careful examination being made, mainly for the purpose of determining whether the tubes were distended, a free incision was made through the hymen, which was about 3-16 of an inch in thickness, and forty ounces of thick, chocolate-colored fluid removed. The uterus and tubes were then found unaffected, and the vagina was thoroughly cleansed with a solution of corrosive sublimate, 1 to 2000. This canal was filled with iodoform gauze, and the patient put to bed.

Subsequently, the temperature was never but once above the normal, which was on the evening of the second day, when it scored 99.5°. The iodoform dressings were changed each second day, which not only insured the cleanliness of the vagina, but promoted the healing of its walls, which were much thickened and granular, bleeding easily, but also in their application and removal, insured against any closing again of the hymen. She returned home in two weeks, and from letters received both from Dr. Towne and her husband, I am assured of her health and happiness. She menstruated but once after the operation, becoming pregnant almost immediately.

By the kindness of the late Dr. J. B. S. Jackson, my attention was called, some years ago, to a most remarkable specimen in the Museum of the Medical Improvement Society, which was removed *post-mortem*, the case having been under his care, and seen by several of the most prominent surgeons of this city practising thirty years ago. Both the uterus and vagina were dilated in this case to such an extent, that the fundus of the uterus reached the umbilicus; the Fallopian tubes also were greatly distended, feeling like sausages on either side of the uterus. Although the condition was recognized by all, yet non-interference was advised, and the patient succumbed to her disease.

In the treatment of the class of cases under consideration, I am sure that it is essential to determine whether the tubes, as well as the uterus and vagina, are distended by the retained menstrual flux, for if so, it will not be safe to make a free incision and empty the uterus and vagina, for either septicæmia will occur from the tubes, or there will be great danger of their rupture occurring from the increased peristalsis of their walls, excited into action by the contracting uterus. If, then, such condition be present, it would be best first to remove the distended tubes by laparotomy, and then make the free incision through the hymen, and empty the uterus and vagina. If, however, the retention of the fluid does not extend to the tubes, the case may be treated simply by evacuating the vagina, or vagina and uterus, and keeping the walls clean and the opposing walls from uniting by adhesive inflammation.

RECENT PROGRESS IN THE CARE OF THE INSANE.

BY WALTER CHANNING, M.D.

INSANE CRIMINALS.

"THE Connection between Crime and Insanity"[1] is the name of a new book by Sander and Richter, reviewed by Dr. Pelman, who remarks that it has been an accepted fact among physicians who care for the insane, that criminals, who become insane while undergoing sentence, are not fit subjects for insane institutions. Nevertheless, in prison they occasion great trouble, and cannot be prevented from outbreaks of insanity. Whatever plans have been proposed for their provision, the opinion has been pretty unanimous to keep them out of asylums.

Dr. Sander, in his book, takes the opposite ground, and says that, in his opinion, special institutions for the criminal insane are not necessary. Dr. Sander's field of labor is at the great asylum at Dalldorf, where the observations embodied in his book have been made, and they certainly demand serious consideration.

From outside observation of affairs at Dalldorf, Pelman thinks the opposite opinion from that of Dr. Sander would be formed. And this would be strengthened by the communication of Sommer, in 1884, which described the trouble that had arisen from bringing insane criminals together at Dalldorf, in consequence of which it had been necessary to obtain the services of two prison officials, who, to a certain extent, acted as overseers of the division devoted to the care of this class.

Dr. Richter, in the first part of Dr. Sander's book, gives a history of 190 criminals treated at Dalldorf from 1880–1883. The number among these who made attempts to escape is considerable, while not a few succeeded, and others misbehaved themselves. The impression made on Pelman by reading the report of these cases, is that they are not fit subjects for a lunatic asylum.

Sander found that 75 per cent. were in an insane condition when they were sentenced. In only thirty-eight cases were the patients' condition discovered at the time of trial, so that the chance of being unfairly sentenced was only one in three. Out of fifteen paralytics, four only were discovered to be such!

There were six times as many persons among the insane in the institutions of Berlin, who had undergone criminal prosecution, as among the generally healthy population of Prussia, which, Sander thinks, demonstrates the close connection between insanity and crime.

Only eight per cent. were more dangerous and troublesome than the ordinary insane, but the women are left out in this estimate.

[1] Die Beziehungen zwischen Geistesstörung und Verbrechen. Von Dr. W. Sander and Dr. A. Richter, Berlin, 1886. Besprochen, von Dr. Pelman. All. Zeitschrift f. Psychiatrie. 22tes. Band, 4tes Heft.

In the smaller institutions, Sander thinks one or two rooms fitted up more strongly than the others will be sufficient for the criminal insane. In the larger institutions, an annex, or a connected building, or ward especially arranged for this class, will be sufficient.

Be the form of arrangement what it will, it is especially important to consider the question of prophylaxis, or how the production of this class of persons can be prevented. They are punished and kept for years in prison, to be finally sent to insane asylums.

Physicians acquainted with insanity should be present at the examination of the inmates of, at least, the large prisons. The judge should also turn his attention more than has previously been the case, to the mental condition of criminals coming before him, especially in young persons, and he need exercise less care in regard to simulation.

The Trustees of the Worcester Lunatic Hospital again express their very strong disapproval of treating the criminal with the ordinary insane.[2] They say that the first movement toward relieving the overcrowding of the Massachusetts hospitals should be in the direction of separate provision for insane criminals. "That they should be treated upon the same terms as, and allowed to associate with those innocent of criminal act, or thought, is opposed to every sentiment of propriety and justice. . . . No criminal, insane or otherwise, should be sent to serve out his sentence to a hospital designed and constructed for the care and cure of innocent and respectable persons, who are so unfortunate as to be sick in mind."

The Trustees think that there is land enough in connection with all the State insane hospitals, upon which buildings might be erected suitable for the treatment of insane criminals. Such buildings could be large enough for two hundred to two hundred and fifty persons, and need not cost more than $300 or $400 per bed, and they could be supervised and managed by the officers of the general hospital.

At the Maine Insane Hospital,[3] they "suffer very sensibly" from the presence of twenty-eight insane criminals, and the superintendent thinks it would be wise to erect a separate building for them.

Dr. Eugene Grissom, Superintendent of the North Carolina Insane Asylum, is very emphatic in what he says regarding the association of the criminal with the common insane.[2] "The repeated decisions of the courts sending persons accused of grave crimes to this institution upon a verdict of insanity, are gradually filling our wards with cases that are unfit to be associated with the virtuous insane." In his Report for 1872, he referred to the same evil, and now says that it has been steadily growing in magnitude since that time.

He thinks that the establishment of proper quarters for the criminal insane within the limits of the penitentiary, would tend to diminish the burdens of the courts, and make criminals and their friends less anxious for their acquittal on the ground of insanity.

The Morristown, New Jersey, Asylum also has a number of the criminal insane.[2] Of these the Superintendent writes:— "While some of them are undoubtedly persons whose crime is the outgrowth of their insanity, and are not more troublesome than other insane persons of the same class, others properly belong to the criminal class, with all their propensities in full vigor, in some cases, intensified by their insanity. . . . The ordinary wards of an asylum . . . are not fitted by their construction for the detention of such crafty and determined men. For them there should be provided, either in connection with the prison, or with one of the asylums, a ward, or wards of greater strength and security. . . . The need of such provision is also great for such persons as escape conviction from crime on the ground of insanity. . . ."

Dr. Godding, Superintendent of the Government Hospital for the Insane, at Washington, now has forty-three insane criminals under his charge.[2] The hospital has no special department for this class; therefore, they are, of necessity, placed among the ordinary insane. This is all wrong, Dr. Godding thinks, as insanity is not a crime, and should never be regarded as such. The protection of the community makes it necessary that insane criminals should be securely guarded, but "the professional burglar, overtaken by insanity, and sent to the hospital, smiles, in his lucid moments, at the window-guards of the dormitory, as if they could ever be thought to represent confinement for him."

CONGRESS OF CRIMINAL ANTHROPOLOGY, ROME, NOVEMBER, 1885.[4]

Dr. Motet who presented the report says that all the young students of medicine and law in Italy are deeply influenced by Professor Lombroso, author of the "L'Momo delinquente." The Congress called for discussion of the above subject in the new light thrown upon it by him and others in late years. The question resolves itself into two parts — criminal biology and criminal sociology. The former embraces the study of the criminal in his organic and phychical conditions, and the latter considers how society may best protect itself against him who endangers its security or repose.

Criminal biology. Professor Lombroso laid great weight upon atavism, and Professor Benedikt, of Vienna, said that neurasthenia dominates the whole system of the criminal. He considered insanity and crime such close neighbors, that he proposed to replace the expressions, "culpability" and "punishment" by "harmfulness or danger to society" and "the right of prevention or preservation."

Professor Lombroso exhibited a large number of skulls and passed in review the principal anomalies of development which he said were more frequently met with in criminals than elsewhere.

M. Ferri distinguished two classes of criminals; the instinctive criminal and the criminal from passion. He said that the insane criminal belonged to the former class. The instinctive criminal is almost always precocious, but the others almost always commit the first crime between the ages of twenty and thirty. From a social point of view, crime is a more profound degeneracy than insanity, since most of the insane are not dangerous, their moral sense having survived the wreck of intelligence.

Professor Sergi considered the question whether there exists a bio-pathological character which predisposes to crime. Criminals often are found to have disease of the nervous system, particularly of the brain. He took for his guide this maxim, "Every sign of morphological degeneracy is also a sign of functional degeneracy."

Prof. Roméo Taverni insisted on the influence of a well-ordered education in producing a well-balanced mind, and also thought that criminals in prisons should

[2] Annual Report, 1885.
[3] Annual Report for 1885.
[4] Annales Medico-Psychologiques Mars, 1886.

be carefully classed in order to prevent the pernicious effect of placing those charged with milder offences among hardened criminals.

M. Morselli, whose studies on suicide are well known, sustained with great talent a theory which excited many objections. He believes in the antagonism of homicide to suicide. He concludes that if there sometimes is parallelism between the two, there is usually antagonism. It does not seem to us that the statistics of France show this. This question is still a study. (I think this antagonism means that when homicide increases, suicide decreases, and vice versa.)

M. Frigerio said that the born criminal belonged to the epileptic family. The Congress in general did not admit the correctness of this view. The question of simulation led the Congress to express the wish that a special place might be reserved in prisons and asylums where might be kept and observed, every individual suspected of simulating insanity. The Congress also expressed the wish that a museum of criminal anthropology might be formed.

The Congress, without discussion, declared that it was in favor of having measures taken to admit to the penitentiaries professors and students for the study of criminal science.

Professor Lacassague spoke of the expert physician before the courts, and thought it might be well to allow the accused to chose an expert and oppose him to the physician employed by the government.

Dr. Semal, in the preceding Congress at Antwerp, used the following words: "Why hesitate to face this problem, by assuming the hypothesis which gives to crime and insanity a common origin? Especially as the question seems to have arrived at a point where it can be more safely investigated, since we have left the domain of pure theory to enter the more reliable one of clinical experience. From the bosom of every belief, even if pushed to excess, there issue elements of truth destined in future to form a new system of doctrine." We are at the commencement of a great scientific movement and must not mistake its character. Its chief promotors show a vigor and severity in their plans for the protection of society, which have never been displayed before. Nevertheless the individual is not sacrificed, for if he belongs to a certain type, special measures will be adopted for his improvement, but if it is recognized that he can never improve, that he will always be a social danger, he will then be eliminated at once and forever from the society which he menaces.

(To be continued.)

Clinical Memoranda.

A CASE OF FRACTURE OF THE SKULL FOLLOWED BY ABSCESS.

BY ATHERTON P. MASON, M.D., OF FITCHBURG.

The following case, which occurred in the practice of Dr. George Jewett, of this city, is of more than usual interest as regards its nature, course, and favorable termination. Having watched it closely during the several weeks of my connection with it, and considering it a case well worth reporting, I have prepared the following brief account of it. For the early history I am indebted to Dr. Jewett, who kindly furnished me with notes made by him at the time the patient came to his office.

J. M., laborer, a large, stout Irishman, about fifty years old, came to Dr. Jewett's office on the morning of August 30th, 1885. He had upon the left parietal eminence a contused wound about one and a half inches long, and extending to the bone. He said that the wound had been received the night previous, but was very reticent as to how he came by it. The wound was filled with hair which had evidently been cut off by some instrument with a dull edge or moderately sharp corner. After careful cleansing there was found a depression of the skull, scaphoid in shape, one and a half inches long, one-half inch wide, and one-quarter inch deep in its widest and deepest portions. The man made no complaint of head or other symptoms, except of tenderness when the wound was touched, and Dr. Jewett observed no symptoms referable to disturbance of the cerebral functions. The wound was dressed antiseptically, the patient was informed of its dangerous character, and absolute rest enjoined; any unfavorable symptom was to be immediately reported.

Nothing further was heard of him until September 5th, when he came again to Dr. Jewett's office on account of pain in the wound. A bloody, purulent discharge issued from the injured parts. Patient said *he had worked steadily during the week past without inconvenience.* The wound was dressed as before, and he was told to stay in his house, and on no account to work.

September 7th a messenger came in haste to Dr. Jewett's office, and said that the man had "had a fit." When seen a short time afterwards, he had a small, hard pulse of 100, temperature 101°, and slow, stertorous respiration. Was mainly unconscious, but could be partially aroused with difficulty. Nothing particular known of his morning history, except that he was heard to fall heavily while alone in his room. He gradually regained consciousness to a considerable extent, and early in the afternoon of the 7th, Dr. Jewett asked Dr. C. W. Spring and myself to assist him in operating.

After etherizing, which was accomplished with some difficulty, a free crucial incision was made in the scalp, and the site of injury to bone exposed. The depression was found to be quite smooth, except on one side, where the fractured wall was vertical and somewhat fissured. Moderate continuous pressure with an elevator opened a fissure, which furnished a key to the situation. The fractured wall was found to be separated at the diploë. The outer table was easily removed in small fragments, but the inner was much more disturbed, and was removed with difficulty and very cautiously. Two sharp fragments were found driven vertically through the dura mater into the substance of the brain. When these were removed, a current of pus welled up from beneath the dura; considerable arterial hæmorrhage followed, but was soon arrested by the gentle pressure of a carbolized sponge. Marked arterial pulsation was observed in the brain substance. The wound was dressed antiseptically with moderate pressure. Patient came out of the ether well, and was tolerably rational at our departure.

September 8th. Passed a rather wakeful night. Pulse in the morning full, soft, 100, temperature 99°. Some hæmorrhage from wound; some confusion of ideas. Same condition at evening visit.

September 9th. Pulse 80, temperature normal,

mind clear, right side of face partially paralyzed, slight aphasia.

During the following week there was some pain in head, slight fever, and gradual increase in paralysis and aphasia. Food accumulated in the right side of the mouth, patient did not seem to possess the power to put out his tongue, right arm and hand became partially paralyzed, and his mind was considerably confused, though there was no delirium at any time. The wound was dressed daily, and preserved a healthy appearance throughout. Moderate secretion of pus. Treatment consisted of tonics and Potass. Bromid. Paralysis and aphasia reached their acme about September 18th, and after that steadily decreased, both being almost entirely gone by the end of the month.

During the last week or ten days of September he had quite an attack of erysipelas, which began in his left ear, and crossed over to the right side. The swelling was considerable, and both his eyes were closed for a day or two. The redness and swelling reached nearly to the margin of the wound, but did not invade it. Glycerine was used locally, and Tr. Fer. chlor., gtt. viii, every four hours, administered internally during the erysipelatous attack, which had the average duration of the simple cutaneous form of the affection. The progress of healing went on favorably in the wound which was completely closed about the middle of October. Just prior to its closure there was necrosis of a portion of the edges of the bone, and several fragments came away. The urine was examined several times during the progress of the case, and always found to be normal.

In the foregoing account the salient points in the case have been briefly described, but no attempt has been made to give a complete record. Two features of the case impressed themselves upon my mind, namely, (1) that this man, having two sharp fragments of bone driven through the dura and into the brain, thereby giving rise to hæmorrhage and the production of pus, could work steadily for a week after the reception of the injury, and displayed no special cerebral symptoms until the eighth day after the injury, at which time cerebral symptoms of a serious nature were apparently suddenly developed. (2) That the erysipelas did not appear in the wound or attack it at all. The erysipelas was severe and exudation rapid as evinced by the appearance of vesicles filled with serum during the progress of the attack. These were most abundant on the ear, the place of beginning.

When last seen in November, the patient was about enjoying life and apparently in as good health and condition as one could desire.

A CASE OF FRACTURED SKULL, WITH AUTOPSY.

BY W. D. BIDWELL, A.M., M.D., (HARV.), LEAVENWORTH, KAN.

In an altercation between C. H. Young and R. B. Gray at five o'clock in the afternoon of Thursday, February 11th, Young struck Gray in the head three times with his left fist, on the little finger of which was a large seal ring. Shortly afterwards Gray left the house, and after riding home, put up his horse and went to a saloon about a mile distant, where he said he felt dizzy and wanted to lie down. It was then after six o'clock. When the saloon was closed at ten o'clock it was found to be impossible to rouse him and a physician was summoned, who arrived at one o'clock and found him perfectly unconscious and with a temperature of 101°. Cold applications to the head were ordered and the patient kept quiet. The patient being in the same condition at ten o'clock the next morning, (February 12th) his father had him carried home on a bed improvised in an express wagon. He was first seen by the writer at one o'clock, when he presented the following symptoms:

Temperature in the axilla, 102°; respirations, 40 to the minute, pulse 80, breathing stertorous, left pupil dilated, both pupils without reaction to light, some rigidity of the muscles of the extremities and free perspiration. There was a cut about one inch long and a quarter of an inch deep over the left malar bone, a slight bruise on the left forehead close to the hair, a slight contusion of the concha of the left ear, and a bruise with moderate swelling above and behind the left ear. At five o'clock the temperature was 102.8°, respirations, 40 to the minute, and pulse 92 and full. No other change in his condition could be detected. A diagnosis of compression of the brain from hæmorrhage had been made, but the external marks of violence were so slight that the brain injury could not be localized, and it was deemed advisable not to resort to operative measures. At seven o'clock, his position was changed owing to difficulty of breathing, and he died without having regained consciousness.

The autopsy was held the following afternoon at five o'clock. Rigor mortis was present. Between the scalp and the skull there was moderate hæmorrhage which had raised the scalp uniformly over an area extending from the forehead to a point a little behind the left ear and half way up on the parietal bone. Just above the external meatus there was a fracture of the squamous portion of the temporal bone which could only be detected from the inside. There was a firm dark clot four inches long, three and one-half inches wide and one inch thick at the middle, lying between the skull and dura mater, compressing the brain over an area corresponding to the hæmorrhage outside the skull. There was also a bag of serum at the posterior extremity of this clot containing about one ounce of fluid. The fracture was over the middle meningeal artery which had been torn through by a sharp projecting fragment. If there had been positive information that no injury was received Thursday night save the blow on the side of the head, the trephine would have been used, but the history was not obtained till the day following his death, he having gone some distance from the place where the affray occurred before he became unconscious. The bone in which the fracture occurred will be produced at the trial in the District Court in April.

— In the reports of fertility which are just now exciting the admiration of the medical press, the Naples correspondent of the *Paris Register*, quoted in the *New York Medical Abstract*, leaves all rivals several lengths in the rear. He says: "Twenty-five miles from here lives Maddalena Granata, aged forty-seven, who, at twenty-eight, married a peasant of nineteen. She has given birth, dead and alive, to fifty-two children, forty-nine of whom were males; she is healthy and robust, and twenty-four hours after her last accouchement, was ready for her accustomed labor in the field. Fifteen times she gave birth to triplets."

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

FEBRUARY 13, 1886, the President, DR. A. D. SINCLAIR, in the chair.

DR. W. H. BAKER reported a case of

IMPERFORATE HYMEN WITH RETENTION OF THE MENSTRUAL FLUX.[1]

DR. COTTING alluded to a case he had seen thirty years ago, that of an unmarried woman, sixteen years of age, suffering with periodical pain and retention of urine, and reported to be pregnant. He found that the hymen was imperforate and bulging, and there was an abdominal tumor as large as a child's head. The patient entered the Massachusetts General Hospital in the service of Dr. J. Mason Warren, who first drew off the retained menstrual fluid with a trocar and then made a crucial incision through the hymen. The incisions so nearly healed in a few days that it was necessary to remove a circular piece from the hymen to prevent its complete closure. The patient had no trouble afterwards, and the catemenia were regular; but she never became pregnant.

DR. STRONG said that in Dr. Baker's case the condition of the vagina was striking. The enlarged villi bled easily and secreted healthy pus: this secretion gradually diminished, however, and the villi subsided, so that when the patient was discharged there was only slight leucorrhœa. The vulvar orifice remained patent and the speculum caused no pain.

DR. BLAKE said that before the day of antiseptics most patients with imperforate hymen died after operation of peritonitis and septicæmia: such cases were therefore much dreaded by surgeons.

DR. J. G. DEARBORN, of Charlestown, reported, by invitation, the following case of

VERMIFORM-APPENDICITIS AND GENERAL PERITONITIS, COMPLICATING THE PUERPERAL PERIOD.

Mrs. G., aged twenty-four, after an unusually rapid labor, was delivered of a healthy female child at 6 P.M., January 17th. This was her second pregnancy. Her health up to the time of this confinement had been good. My next visit was at noon of the following day. She had taken the usual nourishment. There had been a free evacuation of the bowels and she had passed urine twice. Her condition seemed to be in all respects satisfactory. At 10 P.M., I was summoned and found her in great pain. The pains were spasmodic in character and seemed to be located chiefly in the lower part of the abdomen, but sometimes shifted to other portions. Abdomen tympanitic over upper portion, but not swollen nor was the pain increased by pressure. Ordered hot applications to the abdomen, and an enema of warm water. A considerable discharge of gas followed the enema, giving temporary relief. Hot applications were continued and presently another enema was given. This afforded some further relief, but the pain was still quite severe. Morphia was then administered, with directions to repeat the dose until relief was obtained. Tuesday, the 19th, very little pain in the morning. Abdomen not swollen, sensitive to a light touch; but deep pressure caused no increase of pain. Lochia deficient. Warm vaginal douches were given and an enema morning and afternoon. No action of the bowels. Pulse full and regular. Pain returned in the afternoon, but was easily checked by morphia.

During this and the two succeeding days the pulse varied between 88 and 96, and the temperature taken twice daily (in the mouth) was never above 100° F., nor below 99°. Wednesday, the 20th, abdomen sensitive to pressure only over lower portion, tympanitic, but not swollen. Breasts contained some milk, and she began to nurse her child. Lochia still deficient. Severe pain in the afternoon. Morphia as before. At 8 P.M., Dr. F. Minot saw her in consultation. Morphia continued during the night as required, and she had some sleep.

Condition on Thursday, the 21st, substantially unchanged. Very little pain during the day. One-half ounce of castor oil given in the morning. Vomited a small quantity of mucous twice during the day, but was able to retain all articles of food and drink. Friday, the 22d, pulse 96, morning temperature (in axilla) 100.2°, evening 100.7°. Some swelling of abdomen, moderate tenderness on pressure. No secretion of milk. Vomited once about four ounces of liquid tinged with bile. Citrate of magnesia given in the morning: in the afternoon an anema brought away a small quantity of fæcal matter.

At 9.30 P.M., Dr. W. L. Richardson saw her in consultation. With the view of obtaining a thorough action of the bowels five grains of calomel and six grains jalap were administered at 11 P.M. Saturday, the 23d, I was summoned at 5 A.M., and found her restless, but without pain. Pulse 140, small, thready, and at times almost imperceptible. Temperature 97.8°. Facial expression anxious: swelling of abdomen considerably increased, but walls not tense: extremities cold. There had been no action of the bowels. Under the use of stimulants the pulse at 8 A.M., had become stronger and slower, and her general appearance somewhat improved; but at 11 A.M. vomiting began. From this time she sank rapidly and died at 12.30.

DR. GANNETT, who made the autopsy, described the appearances presented:

Death resulted from general peritonitis, occurring in a puerperal woman one week after delivery; but it was not a case of puerperal peritonitis; that is, the source was not the uterus or vagina, but was wholly independent of the generative organs, which showed a normal condition for that period after the birth of the child.

The origin was found in an inflammation of the vermiform appendix, appendicitis. This organ was doubled in diameter: on opening, it was found to contain a grayish, pap-like material; the mucosa was much thickened, reddened, injected, and in parts hæmorrhagic. At the neck there was a constriction: at this point there was a marked loss of substance of the mucosa, the base being black in color. The peritonæum of appendix covered by recent fibrinous false membranes; around it, in the cavity of the pelvis was a small amount of pus.

The cavity of the pelvis was shut off from the rest of the abdominal cavity by the adhesion of the wall of the uterus and folds of intestine to the brim of the pelvis by recent fibrinous false membranes. The lower twenty-four inches of the ileum were contained in the pelvis; the folds of this portion were united by fibri-

[1] See page 290.

no-purulent material. The remaining portion of small intestine, which was free in the abdominal cavity, was greatly distended with gas and liquid contents. The peritoneal surface showed the presence of a thin fibrinous false membrane, but the coils were not adherent to each other.

The peritonæum covering the spleen and liver showed a much thicker fibrinous false membrane upon its surface. The heart, kidneys and liver showed evidences of a cloudy swelling: the spleen hyperplastic to a moderate degree.

One has to do in this case with an acute catarrhal-hæmorrhagic inflammation of the mucous membrane of the vermiform appendix with ulceration; the inflammatory process then extending to the peritoneal surface and in turn leading to a general peritonitis.

DR. W. L. RICHARDSON said that when he saw the case he considered it one of septicæmia, although he could not find evidences of any uterine or ovarian trouble. He was influenced in his opinion by the sudden arrest of the lochia, followed by a rise of temperature and abdominal tenderness. A vaginal examination, however, showed the uterus to be of normal size and not tender, nor was there any evidence of inflammation in the region of the ovaries on examination *per vaginam*. He had closely questioned the patient as to her health prior to the confinement, but could not ascertain that she had been otherwise than in perfect health. After her death her husband had stated that she had been for a week before her confinement complaining of pain in the right iliac region. The doubt in his mind had been whether there might not be some intestinal obstruction; but the fact that she had had free operations from the bowels since the attack, had ruled that out. Although he had considered it a case of septicæmia he had advised against any uterine treatment, inasmuch as he could find no evidence pointing to the uterus as the source of the trouble.

In reply to a question by Dr. Abbott, Dr. Dearborn said that the patient had had a sense of fatigue and weariness in the right iliac fossa for two or three weeks before labor; still she declared she was in good health up to the time of her delivery.

DR. F. B. HARRINGTON reported, by invitation, a case of

SEVERE HÆMORRHAGE FROM ANTE-PARTUM SEPARATION OF THE PLACENTA, WITH THE INFUSION OF SIXTY-SIX OUNCES OF SALT SOLUTION.[2]

DR. W. L. RICHARDSON said that he had seen the patient this afternoon. Her pulse was good and her general appearance was that of a patient convalescing from some sickness of moderate severity. He would never have thought that she had so recently suffered from a hæmorrhage which would certainly have proved fatal but for the prompt and skilful treatment which Dr. Harrington had used. The wounds in both arms had perfectly healed.

DR. REYNOLDS spoke of the great value of electricity in post-partum hæmorrhage, and thought the obstetrican should never go to a case of labor without taking with him a battery in working order. He said it was unsafe to tampon the vaginam *post partum*, unless the uterus was held so as to prevent its filling up with blood.

DR. STRONG said that after the application of the first tampon, the uterus was supported for more than an hour and remained well contracted, and it therefore seemed safe to remove the hand. The post-partum hæmorrhage was not excessive and would have caused no alarm, if the patient had not been so much depleted by the ante-partum hæmorrhage. There was great difficulty in dilating the cervix: the pains had only very slight effect on it, and it seemed just before the cervix tore that it would have to be incised. Comparatively little was known of the value of salt infusion; but in this case the patient would undoubtedly have died, if this treatment had not been promptly resorted to.

[2] The paper appeared in the Journal of March 4, page 197.

A NEW CEPHALOTOME.

DR. EDWARD REYNOLDS, Senior House-Officer of the Boston Lying-in Hospital, exhibited, by invitation, a cephalotome of his invention, and explained its construction and use:—

The object to be aimed at, in the construction of any instrument for decapitation, is two-fold: first, the avoidance of danger to the soft parts of the mother; and second, a rapid and easy division of the neck of the child.

The instrument in question is, in principle, merely a large and powerful écraseur, modified by substituting for the blunt end of the ordinary écraseur, a crescentic knife one and one-half inches wide, which terminates on either side in a blunt point, designed to protect the maternal parts from injury during the introduction and withdrawal of the instrument. Each of these projecting horns bears upon its inner surface a deep slot, fitted to receive the ends of a loop of No. 18 steel piano wire, which has been found upon trial to be admirably suited to the purpose, since it possesses at once great strength and sufficient flexibility. The necessary power is furnished by a steel axle, with transverse handle, fitted with a ratchet, and pierced by a hole, through which the wire is passed.

The capacities of this decapitator are easily appreciated by remembering that as soon as the instrument is in position, the neck is in the grasp of an iron circle, about one-third of which is formed by a sharp, cutting edge, against which it is drawn by the shortening of the loop, with a force limited only by the strength of the wire; and this without the slightest danger of implicating the soft parts of the mother.

The operation consists of two steps: first, the passage of the wire around the neck of the child, and its adjustment to the decapitator; second, the division of the neck, and the withdrawal of the instrument, followed, of course, by the extraction of the child in the usual manner. The introduction of the wire is most conveniently effected by an instrument copied from Ollivier's porte-fillet, but modified

by increasing its size, and by substituting for the whalebone stylet of Ollivier's model, a piece of wire — wound piano-wire, which possesses the advantage of being so cheap that it can be thrown away after use, and replaced by another piece, thus greatly facilitating the cleansing of the tube. It moreover reduces the cost of the instrument by more than two-thirds of its price. While the porte-fillet is a convenience in placing the wire in position, it is not a necessity, as an English catheter can be made to answer the same purpose. To this end a loop of narrow tape is passed through the catheter, protruding two inches from its eye. The catheter is softened in warm water, bent to the shape of a blunt hook, and placed about the neck; and is then pushed up along its stylet until the free end bearing the tape is within easy reach of the finger.

The wire should be from three to four feet in length and should be twisted at one end into an eye. In introducing it the looped end should pass behind the neck; and the ends of the wire being drawn well outside the vulva, to render manipulation easy, are then passed through the slot behind the knife of the decapitator. The looped end of the wire is next attached to the hook on the posterior side of the shank of the instrument, while the free end is passed through its handle and through the hole in the axle of the crank. The assistant fastens the wire by giving it one turn backwards around the axle and cuts off its superfluous length. The operator then grasps the instrument in the right hand, and, guarding the knife by placing two fingers of the left hand upon its blunt point passes it into the vagina. He next satisfies himself that the knife is properly adjusted to the neck, that the wires rest securely in their respective slots, and that no fold of the maternal tissues is included in their grasp; then the assistant slowly winds up the crank, under the direction of the operator, who, with two fingers in the vagina, makes sure that the knife maintains its proper relations to the neck and to the wire loop. A sudden relief of the tension upon the wire announces that the neck is severed, and the instrument is then carefully withdrawn.

Dr. William L. Richardson has twice performed the operation upon the cadaver, with most satisfactory results. The introduction of the wire and its adjustment to the cephalotome occupies but three or four minutes, and the decapitation proper is extremely rapid, so much so, that at Dr. Richardson's second trial of the instrument, it was in the vagina but twenty-five seconds, although no attempt at speed was made. The knife seems to pick out the point of least resistance in the neck, for at both trials it passed between two vertebræ, dividing the intervertebral substance, and making a perfectly smooth section, free from spiculæ of bone; thus, of course, greatly diminishing the risks of the extraction.

This instrument, then, appears to be capable of accomplishing the decapitation with much greater ease and rapidity than those in common use, and with far less of danger to the mother. It has been suggested that, by inserting a joint in the shank of the cephalotome to allow of the attachment of a longer shaft with pelvic curve, the operation might be extended to cases in which the neck is so high as to be out of the reach of any straight instrument. Such a shaft would necessarily be provided with a groove or with rings to guide the wire along the curve, and could easily be made by any instrument maker. Messrs. Leach and Greene are prepared to furnish these instruments to the profession, if desired.

DR. W. L. RICHARDSON said that, in addition to the reasons given by Dr. Edward Reynolds, there was this great advantage in the instrument. Whether one uses the decapitating knife of Ramsbotham, Jr., or the hook of Braun, there is more or less danger of injuring the soft parts of the mother by the movements of the fœtus which the use of these instruments involves. This new instrument holds the fœtus firmly in position, and the rapidity of the decapitation is remarkable. At the time he had used it on the cadaver he was not aware that he was being timed, but was doing the operation much slower than he could have done it, with a view of making as central an excision as possible.

In this connection he showed an instrument improvised by Mr. J. W. Craig, of the Medical School, for doing the same operation by the same method Dr. Reynolds had proposed, but with a home-made instrument, such as could be made impromptu in any house. The one he showed had taken thirty-five minutes to make with a hammer and file, and had cost forty cents. It consisted only of a hollow tube, at one end of which a notch had been cut on either side; through this tube the bent wire had been passed and the ends made fast to a bent piece of iron which fitted into the two notches. On turning this iron the wire was twisted tighter and tighter around the fœtal neck until it was severed.

RHODE ISLAND MEDICAL SOCIETY.

THE usual quarterly meeting was held in Providence, March 18, 1886, the President, Dr. O. C. Wiggin, in the chair.

The President announced the appointment of Dr. Albert Potter to serve as second Vice-President in place of Dr. J. W. Sawyer, deceased.

Dr. William B. Goldsmith, recently appointed Superintendent of the Butler Hospital for the Insane, was elected a Fellow.

Delegates to the American Medical Association were appointed as follows: Drs. O. C. Wiggin, H. G. Miller, E. T. Caswell, W. E. Anthony, H. Canfield, H. R. Storer, C. V. Chapin, S. Hunt, M. Fifield, W. R. White, J. Kenyon, G. H. Kenyon, J. H. Morgan, G. R. Smith, A. B. Briggs, D. O. King. A motion to instruct the delegates as to their attitude towards the preliminary organization of the International Medical Congress of 1887 failed of adoption.

DR. H. R. STORER exhibited a large vaginal fibroid tumor weighing one and a half pounds and of the size, shape and general appearance of an ox-heart, which he had removed five days previously from a healthy woman, aged thirty-five, a patient of Dr. J. P. Curley, of Newport. The growth was continuous with the cervix anteriorly and to the left and entirely occluded the vagina. From the fact that the uterus could not be felt above the pubes in its natural central position it was at first feared that the case might be one of the rare instances of spontaneous uterine inversion. Dr. Storer found the depending portion of the tumor soft, compressible and friable, like true uterine tissue, and that a female catheter would but partially enter the bladder, in these respects simulating inversion, but he finally settled the diagnosis by getting a sound past the tumor and into the uterus which was crowded over obliquely to the right.

After the tumor had been cut away with an ecraseur, which was virtually a bloodless operation, it could be rotated in the vagina but could not be extracted with the small forceps at hand. Forcibly dilating the sphincter ani the operator introduced his arm into the rectum, the fingers having to enter the sigmoid flexure before sufficiently expulsive leverage could be exerted. Under this added force, the forceps delivered the tumor.
